Alternating Automata Modulo First Order Theories

Abstract. We introduce first order alternating automata, a generalization of boolean alternating automata, in which transition rules are described by multisorted first order formulae, with states and internal variables given by uninterpreted predicate terms. The model is closed under union, intersection and complement, and its emptiness problem is undecidable, even for the simplest data theory of equality. To cope with the undecidability problem, we develop an abstraction refinement semi-algorithm based on lazy annotation of the symbolic execution paths with interpolants, obtained by applying (i) quantifier elimination with witness term generation and (ii) Lyndon interpolation in the quantifier-free theory of the data domain, with uninterpreted predicate symbols. This provides a method for checking inclusion of timed and finite-memory register automata, and emptiness of quantified predicate automata, previously used in the verification of parameterized concurrent programs, composed of replicated threads, with shared memory.

1 Introduction

Many results in automata theory rely on the finite alphabet hypothesis, which guarantees, in some cases, the existence of determinization, complementation and inclusion checking methods. However, this hypothesis prevents the use of automata as models of real-time systems or even simple programs, whose input and output are data values ranging over very large domains, typically viewed as infinite mathematical abstractions.

Traditional attempts to generalize classical Rabin-Scott automata to infinite alphabets, such as timed automata [1] and finite-memory automata [14] face the *complement closure* problem: there exist automata for which the complement language cannot be recognized by an automaton in the same class. This makes it impossible to encode a language inclusion problem $\mathcal{L}(A) \subseteq \mathcal{L}(B)$ as the emptiness of an automaton recognizing the language $\mathcal{L}(A) \cap \mathcal{L}^c(B)$, where $\mathcal{L}^c(B)$ denotes the complement of $\mathcal{L}(B)$.

Even for finite alphabets, complementation of finite-state automata faces inherent exponential blowup, due to nondeterminism. However, if we allow universal nondeterminism, in addition to the classical existential nondeterminism, complementation is possible is linear time. Having both existential and universal nondeterminism defines the *alternating automata* model [4]. A finite-alphabet alternating automaton is described by a set of transition rules $q \xrightarrow{a} \phi$, where q is a state, a is an input symbol and ϕ is a boolean formula, whose propositional variables denote successor states.

Our Contribution We extend alternating automata to infinite data alphabets, by defining a model of computation in which all boolean operations, including complementation, can be done in linear time. The control states are given by k-ary predicate symbols $q(y_1, \ldots, y_k)$, the input consists of an event a from a finite alphabet and a tuple of data variables $x_1, \ldots, x_n$, ranging over an infinite domain, and transitions are of the form $q(y_1, \ldots, y_k) \xrightarrow{a(x_1,\ldots,x_n)} \phi(x_1, \ldots, x_n, y_1, \ldots, y_k)$, where ϕ is a formula in the first-order theory of the data domain. In this model, the arguments of a predicate atom $q(y_1, \ldots, y_k)$ represent the values of the *internal variables* associated with the state. Together with the input values $x_1, \ldots, x_n$, these values define the next configurations, but remain invisible in the input sequence.

The tight coupling of internal values and control states, by means of uninterpreted predicate symbols, allows for linear-time complementation just as in the case of classical propositional alternating automata. Complementation is, moreover, possible when the transition formulae contain first-order quantifiers, generating infinitely-branching execution trees. The price to be paid for this expressivity is that emptiness of first-order alternating automata is undecidable, even for the simplest data theory of equality [5].

The main contribution of this paper is an effective emptiness checking semi-algorithm for first-order alternating automata, in the spirit of the IMPACT lazy annotation procedure, originally developed for checking safety of nondeterministic integer programs [18,19]. In a nutshell, a lazy annotation procedure unfolds an automaton A trying to find an execution that recognizes a word from $\mathcal{L}(A)$. If a path that reaches a final state does not correspond to a concrete run of the automaton, the positions on the path are labeled with interpolants from the proof of infeasibility, thus marking this path and all continuations as infeasible for future searches. Termination of lazy annotation procedures is not guaranteed, but having a suitable coverage relation between the nodes of the search tree may ensure convergence of many real-life examples. However, applying lazy annotation to first order alternating automata faces two nontrivial problems:

1. Quantified transition rules make it hard, if not impossible, in general, to decide if a path is infeasible. This is mainly because adding uninterpreted predicate symbols to decidable first-order theories, such as Presburger arithmetic, results in undecidability [9]. To deal with this problem, we assume that the first order data theory, without uninterpreted predicate symbols, has a quantifier elimination procedure, that instantiates quantifers with effectively computable *witness terms*.
2. The interpolants that prove the infeasibility of a path are not *local*, as they may refer to input values encountered in the past. However, the future executions are oblivious to *when* these values have been seen in the past and depend only on the relation between the past and current values. We use this fact to define a labeling of nodes, visited by the lazy annotation procedure, with conjunctions of existentially quantified interpolants combining predicate atoms with data constraints.

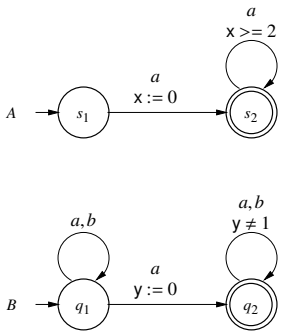
Applications We use first order alternating automata to develop practical semi-algorithms for a number of known undecidable problems, such as: inclusion of regular timed languages [1], inclusion of quasi-regular languages recognized by finite-memory automata [14] and emptiness of predicate automata, a subclass of first-order alternating automata used to verify parameterized concurrent programs [5,6].

Consider, for instance the problem of proving that $\mathcal{L}(A) \subseteq \mathcal{L}(B)$, where A and B are the timed automata in Fig. 1. The automaton A (B) has a single clock x (y) which is reset on the transition from s_1 to s_2 (q_1 to q_2). Intuititvely, A recognizes the sequences in which all events are a and the second event, if it occurs at all, it occurs after at least 2 time units. On the other hand, B recognizes the sequences in which there exists an event a such that no event occurs after it in exactly 1 time unit. Formally, $\mathcal{L}(A) = \{a, t_1, \ldots a, t_n \mid t_1, \ldots, t_n \in \mathbb{R},\ n > 1 \Rightarrow t_2 - t_1 \geq 2\}$ and $\mathcal{L}(B) = \{\sigma_1, t_1 \ldots \sigma_{i-1}, t_{i-1}, a, t_i, \sigma_{i+1}, t_{i+1}, \ldots \sigma_n, t_n \mid \sigma_1, \ldots, \sigma_n \in \{a, b\},\ n \geq 1,\ t_1, \ldots, t_n \in \mathbb{R},\ 1 \leq i < n \Rightarrow t_{i+1} - t_i \neq 1\}$. It is proved[1] that $\mathcal{L}^c(B)$ cannot be recognized by a timed automaton, thus the inclusion cannot be proved in the framework of timed automata [1,2], by showing that $\mathcal{L}(A) \cap \mathcal{L}^c(B) = \emptyset$.

Our approach is to encode timed automata as first order alternating automata and use closure of the latter class under intersection and complement to compute an alternating

[1] See [2, Theorem 1] for a proof.

automaton, whose emptiness proves that $\mathcal{L}(A) \subseteq \mathcal{L}(B)$. Consider the encoding of A in Fig. 1 (right) inspired by a translation of timed automata into Datalog programs [8]. Each control state of A and B is represented by a binary predicate symbol with the same name. The first argument of $s_1(x,z)$ tracks the (last) time value time when the x clock of A was reset (if it is reset more than once) and z is the time value of the last event. The time stamp of the current event a is the input variable t, which must be bigger or equal to z, since the lapse of time between two consequtive events is always positive. The current value of the x clock is thus $z - x$ and the guard $\mathsf{x} \geq 2$ on the $s_2 \rightarrow s_2$ transition of A from becomes $z - x \geq 2$ in the second rule. The reset of x on the $s_1 \rightarrow s_2$ transition is encoded by passing z as the first parameter of s_2, in the first rule. The initial configuration of A [B] is $s_1(0,0)$ [$q_1(0,0)$] and s_2 [q_2] marks the final configurations.



$$A\begin{cases} s_1(x,z) \xrightarrow{a(t)} t \geq z \wedge s_2(z,t) \\ s_2(x,z) \xrightarrow{a(t)} t \geq z \wedge z - x \geq 2 \wedge s_2(x,t) \end{cases}$$

$$B\begin{cases} q_1(y,u) \xrightarrow{a(t),b(t)} t \geq u \wedge q_1(y,t) \\ q_1(y,u) \xrightarrow{a(t)} t \geq u \wedge q_2(u,t) \\ q_2(y,u) \xrightarrow{a(t),b(t)} t \geq u \wedge u - y \neq 1 \wedge q_2(y,t) \end{cases}$$

$$\overline{B}\begin{cases} q_1(y,u) \xrightarrow{a(t),b(t)} t < u \vee q_1(y,t) \\ q_1(y,u) \xrightarrow{a(t)} t < u \vee q_2(u,t) \\ q_2(y,u) \xrightarrow{a(t),b(t)} t < u \vee u - y = 1 \vee q_2(y,t) \end{cases}$$

Fig. 1. First Order Alternating Automata Checking Inclusion of Timed Automata

The first order alternating automaton recognizing the (encoding of the) $\mathcal{L}^c(B)$ language is simply obtained by negating the theory atoms $t \geq u$ and $u - y \neq 1$ and interchanging conjunctions with disjunctions in the rules of the alternating automaton encoding B, denoted as $\overline{B}$ in Fig. 1 (bottom right), with final configurations marked by q_1, instead of q_2. Finally, we check the emptiness of the alternating automaton consisting of the rules of A and $\overline{B}$, started in the initial configuration $s_1(0,0) \wedge q_1(0,0)$. Our lazy annotation semi-algorithm proves emptiness of this automaton in ~ 0.3 seconds, on an average laptop machine.

Related Work The first order alternating automata model presented in this paper extends the alternating automata with variables ranging over infinite data considered in [12]. There all variables were required to be observable in the input. We overcome this restriction by allowing internal (invisible) variables. Another closely related work [11] considers an inclusion between an asynchronous product of automata $A_1 \times \ldots \times A_n$, extended with data variables, and a monitor automaton B. The semi-algorithm defined there was based on the assumption that all variables of the observer B must be declared in the automata $A_1, \ldots, A_n$ under check. First order alternating automata bypass this limitation, since our emptiness checking semi-algorithm can handle invisible variables.

The work probably closest to ours concerns the model of predicate automata (PA) [5,6,15], used in the verification of parameterized concurrent programs with shared memory. In this model, the alphabet consists of pairs of program statements and thread identifiers, thus being infinite because the number of threads is unbounded. Since thread identifiers can only be compared for (dis-)equality, the data theory in PA is the theory

of equality. Even with this simplification, the emptiness problem is undecidable when either the predicates have arity greater than one [5] or use quantified transition rules [15]. Checking emptiness of quantifier-free PA is possible semi-algorithmically, by explicitly enumerating reachable configurations and checking coverage by looking for permuations of argument values. However, no semi-algorithm is given for quantified PA. Dealing with quantified transition rules is one of our contributions.

For space reasons, the proofs of the technical results are given in Appendinx B.

1.1 Preliminaries

For two integers $0 \leq i \leq j$, we define $[i, j] \stackrel{\text{def}}{=} \{i, \ldots, j\}$ and $[i] \stackrel{\text{def}}{=} [0, i]$. We consider two disjoint sorts $\mathbb{D}$ and $\mathbb{B}$, where $\mathbb{D}$ is an infinite domain and $\mathbb{B} = \{\top, \bot\}$ is the set of boolean values true ($\top$) and false ($\bot$), respectively. The $\mathbb{D}$ sort is equipped with countably many function symbols $f : \mathbb{D}^{\#(f)} \to \mathbb{D} \cup \mathbb{B}$, where $\#(f) \geq 0$ denotes the number of arguments (arity) of f. A *predicate* is a function symbol $p : \mathbb{D}^{\#(p)} \to \mathbb{B}$ that is, a $\#(p)$-ary relation.

We consider the interpretation of all function symbols $f : \mathbb{D}^{\#(f)} \to \mathbb{D}$ to be fixed by the interpretation of the $\mathbb{D}$ sort, for instance if $\mathbb{D}$ is the set of integers $\mathbb{Z}$, these are zero, the successor function and the arithmetic operations of addition and multiplication. We extend this convention to several predicates over $\mathbb{D}$, such as the inequality relation over $\mathbb{Z}$, and write Pred for the set of *uninterpreted predicates*.

Let $\mathsf{Var} = \{x, y, z, \ldots\}$ be a countably infinite set of variables, ranging over $\mathbb{D}$. Terms are either constants of sort $\mathbb{D}$, variables or function applications $f(t_1, \ldots, t_{\#(f)})$, where $t_1, \ldots, t_{\#(f)}$ are terms. The set of first order formulae is defined by the syntax below:

$$\phi := t = s \mid p(t_1, \ldots, t_{\#(p)}) \mid \neg\phi_1 \mid \phi_1 \wedge \phi_2 \mid \exists x \,.\, \phi_1$$

where $t, s, t_1, \ldots, t_{\#(p)}$ denote terms and p is a predicate symbol. We write $\phi_1 \vee \phi_2$, $\phi_1 \to \phi_2$ and $\forall x \,.\, \phi_1$ for $\neg(\neg\phi_1 \wedge \neg\phi_2)$, $\neg\phi_1 \vee \phi_2$ and $\neg\exists x \,.\, \neg\phi_1$, respectively. $\mathrm{FV}(\phi)$ is the set of free variables in ϕ and the size $|\phi|$ of a formula ϕ is the number of symbols needed to write it down. A *sentence* is a formula ϕ with no free variables. A formula is *positive* if each uninterpreted predicate symbol occurs under an even number of negations and we denote by $\mathsf{Form}^+(Q, X)$ the set of positive formulae with predicates from the set $Q \subseteq \mathsf{Pred}$ and free variables from the set $X \subseteq \mathsf{Var}$. A formula is in *prenex form* if it is of the form $\varphi = Q_1 x_1 \ldots Q_n x_n \,.\, \phi$, where ϕ has no quantifiers. In this case we call ϕ the *matrix* of φ. Every first order formula can be written in prenex form, by renaming each quantified variable to a unique name and moving the quantifiers upfront.

An *interpretation* $\mathcal{I}$ maps each predicate symbol p into a set $p^{\mathcal{I}} \subseteq \mathbb{D}^{\#(p)}$, if $\#(p) > 0$, or into an element of $\mathbb{B}$ if $\#(p) = 0$. A *valuation* ν maps each variable x into an element of $\mathbb{D}$. Given a term t, we denote by t^{ν} the value obtained by replacing each variable x by the value $\nu(x)$ and evaluating each function application. For a formula ϕ, we define the forcing relation $\mathcal{I}, \nu \models \phi$ recursively on the structure of ϕ, as usual. For a formula ϕ and a valuation ν, we define $[\![\phi]\!]_{\nu} \stackrel{\text{def}}{=} \{\mathcal{I} \mid \mathcal{I}, \nu \models \phi\}$ and drop the ν subscript for sentences. A sentence ϕ is *satisfiable* if $[\![\phi]\!] \neq \emptyset$. An element of $[\![\phi]\!]$ is called a *model* of ϕ. A formula ϕ is *valid* if $\mathcal{I}, \nu \models \phi$ for every interpretation $\mathcal{I}$ and every valuation ν. We say that ϕ *entails* ψ, written $\phi \models \psi$ if and only if $[\![\phi]\!] \subseteq [\![\psi]\!]$.

Interpretations are partially ordered by the pointwise subset order, defined as $\mathcal{I}_1 \subseteq \mathcal{I}_2$ if and only if $p^{\mathcal{I}_1} \subseteq p^{\mathcal{I}_2}$ for each predicate symbol $p \in \mathsf{Pred}$. Given a formula ϕ and a valuation ν, we define $[\![\phi]\!]^{\mu}_{\nu} \stackrel{\text{def}}{=} \{\mathcal{I} \mid \mathcal{I}, \nu \models \phi,\ \forall \mathcal{I}' \subseteq \mathcal{I} \,.\, \mathcal{I}', \nu \not\models \phi\}$ the set of minimal interpretations that, together with ν, form models of ϕ.

2 First Order Alternating Automata

Let Σ be a finite alphabet Σ of *input events*. Given a finite set of variables $X \subseteq \mathsf{Var}$, we denote by $X \mapsto \mathbb{D}$ the set of valuations of the variables X and $\Sigma[X] = \Sigma \times (X \mapsto \mathbb{D})$ be the possibly infinite set of *data symbols* (a, ν), where a is an input symbol and ν is a valuation. A *data word* (simply called word in the following) is a finite sequence $w = (a_1, \nu_1)(a_2, \nu_2)\dots(a_n, \nu_n)$ of data symbols. Given a word w, we denote by $w_\Sigma \stackrel{\text{def}}{=} a_1 \dots a_n$ its sequence of input events and by $w_{\mathbb{D}}$ the valuation associating each time-stamped variable $x^{(i)}$, where $x \in \mathsf{Var}$, the value $\nu_i(x)$, for all $i \in [1, n]$. We denote by ε the empty sequence, by Σ^* the set of finite input sequences and by $\Sigma[X]^*$ the set of finite data words over the variables X.

A *first order alternating automaton* is a tuple $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$, where Σ is a finite set of input events, X is a finite set of input variables, Q is a finite set of predicates denoting control states, $\iota \in \mathsf{Form}^+(Q, \emptyset)$ is a sentence defining initial configurations, $F \subseteq Q$ is the set of predicates denoting final states, and Δ is a set of *transition rules*. A transition rule is of the form $q(y_1, \dots, y_{\#(q)}) \xrightarrow{a(X)} \psi$, where $q \in Q$ is a predicate, $a \in \Sigma$ is an input event and $\psi \in \mathsf{Form}^+(Q, X \cup \{y_1, \dots, y_{\#(q)}\})$ is a positive formula, where $X \cap \{y_1, \dots, y_{\#(q)}\} = \emptyset$. Without loss of generality, we consider, for each predicate $q \in Q$ and each input event $a \in \Sigma$, at most one such rule, as two or more rules can be joined using disjunction. The quantifiers occurring in the right-hand side formula of a transition rule are called *transition quantifiers*. The *size* of $\mathcal{A}$ is $|\mathcal{A}| \stackrel{\text{def}}{=} |\iota| + \sum\{|\psi| \mid q(\mathbf{y}) \xrightarrow{a(X)} \psi \in \Delta\}$.

The semantics of first order alternating automata is analogous to the semantics of propositional alternating automata, with rules of the form $q \xrightarrow{a} \phi$, where q is a propositional variable and ϕ a positive boolean combination of propositional variables. For instance, $q_0 \xrightarrow{a} (q_1 \wedge q_2) \vee q_3$ means that the automaton can choose to transition in either both q_1 and q_2 or in q_3 alone. This leads to defining transitions as the *minimal models* of the right hand side of a rule[2]. The original definition of alternating automata [4] works around this problem and considers boolean valuations instead of formulae. In contrast, a finite description of a first order alternating automaton cannot be given in terms of interpretations, as a first order formula may have infinitely many models, corresponding to infinitely many initial or successor states occurring within an execution step.

Given an uninterpreted predicate symbol $q \in Q$ and data values $d_1, \dots, d_{\#(q)} \in \mathbb{D}$, the tuple $(q, d_1, \dots, d_{\#(q)})$ is called a *configuration*, sometimes written $q(d_1, \dots, d_{\#(q)})$, when no confusion arises. A configuration is *final* if $q \in F$. An interpretation $\mathcal{I}$ corresponds to a set of configurations $\mathsf{c}(\mathcal{I}) \stackrel{\text{def}}{=} \{(q, d_1, \dots, d_{\#(q)}) \mid q \in Q,\ (d_1, \dots, d_{\#(q)}) \in q^{\mathcal{I}}\}$, called a *cube*. This notation is lifted to sets of configurations in the usual way.

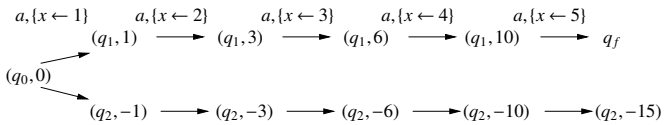
Definition 1. *Given a word $w = (a_1, \nu_1)\dots(a_n, \nu_n) \in \Sigma[X]^*$ and a cube c, an* execution *of $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$ over w, starting with c, is a forest $\mathcal{T} = \{T_1, T_2, \dots\}$, where each T_i is a tree labeled with configurations, such that:*

1. *$c = \{T(\epsilon) \mid T \in \mathcal{T}\}$ is the set of configurations labeling the roots of $T_1, T_2, \dots$ and*
2. *if $(q, d_1, \dots, d_{\#(q)})$ labels a node on the level $j \in [n-1]$ in T_i, then the labels of its children form a cube from $\mathsf{c}([\![\psi]\!]^{\mu}_{\eta})$, where $\eta = \nu_{j+1}[y_1 \leftarrow d_1, \dots, y_{\#(q)} \leftarrow d_{\#(q)}]$ and $q(y_1, \dots, y_{\#(q)}) \xrightarrow{a_{j+1}(X)} \psi \in \Delta$ is a transition rule of $\mathcal{A}$.*

[2] Both $\{q_1 \leftarrow \top, q_2 \leftarrow \top, q_3 \leftarrow \bot\}$ and $\{q_1 \leftarrow \bot, q_2 \leftarrow \bot, q_3 \leftarrow \top\}$ are minimal models, however $\{q_1 \leftarrow \top, q_2 \leftarrow \top, q_3 \leftarrow \top\}$ is a model but is not minimal.

An execution $\mathcal{T}$ over w, starting with c, is *accepting* if and only if all paths in $\mathcal{T}$ have the same length and the frontier of each tree $T \in \mathcal{T}$ is labeled with final configurations. If $\mathcal{A}$ has an accepting execution over w starting with a cube $c \in \mathsf{c}([\![\iota]\!]^\mu)$, then $\mathcal{A}$ *accepts* w and let $\mathcal{L}(\mathcal{A})$ be the set of words accepted by $\mathcal{A}$.

Example 1. Consider the automaton $\mathcal{A} = \langle\{a\},\{x\},\{q_0,q_1,q_2,q_f\},q_0(0),\{q_f\},\Delta\rangle$, where Δ is the set: $q_0(y) \xrightarrow{a(x)} q_1(y+x) \wedge q_2(y-x)$, $q_1(y) \xrightarrow{a(x)} q_1(y+x) \vee (y > 0 \wedge q_f)$ and $q_2(y) \xrightarrow{a(x)} q_2(y-x) \vee (y > 0 \wedge q_f)$. A possible execution tree of this automaton is the following:



The execution tree is not accepting, since its frontier is not labeled with final configurations everywhere. Incidentally, here we have $\mathcal{L}(\mathcal{A}) = \emptyset$, which is proved by our tool in $\sim$0.5 seconds on an average machine. ■

In the rest of this paper, we are concerned with the following problems:

1. *boolean closure*: given automata $\mathcal{A}_i = \langle\Sigma, X, Q_i, \iota_i, F_i, \Delta_i\rangle$, for $i = 1, 2$, do there exist automata $\mathcal{A}_\cap$, $\mathcal{A}_\cup$ and $\overline{\mathcal{A}_1}$ such that $L(\mathcal{A}_\cap) = L(\mathcal{A}_1) \cap L(\mathcal{A}_2)$, $L(\mathcal{A}_\cup) = L(\mathcal{A}_1) \cup L(\mathcal{A}_2)$ and $L(\overline{\mathcal{A}_1}) = \Sigma[X]^* \setminus L(\mathcal{A}_1)$?
2. *emptiness*: given an automaton $\mathcal{A}$, is $L(\mathcal{A}) = \emptyset$?

For technical reasons, we address the following problem next: given an automaton $\mathcal{A}$ and an input sequence $\alpha \in \Sigma^*$, does there exists a word $w \in \mathcal{L}(\mathcal{A})$ such that $w_\Sigma = \alpha$? By solving this problem first, we develop the machinery required to prove that first order alternating automata are closed under complement and, further, set up the ground for developping a practical semi-algorithm for the emptiness problem.

2.1 Path Formulae

In the upcoming developments it is sometimes more convenient to work with logical formulae defining executions of automata, than with low-level execution forests. For this reason, we first introduce *path formulae* $\Theta(\alpha)$, which are formulae defining the executions of an automaton, over words that share a given sequence α of input events. Second, we restrict a path formula $\Theta(\alpha)$ to an *acceptance formula* $\Upsilon(\alpha)$, which defines only those executions that are accepting among $\Theta(\alpha)$. Consequently, the automaton accepts a word w such that $w_\Sigma = \alpha$ if and only if $\Upsilon(\alpha)$ is satisfiable.

Let $\mathcal{A} = \langle\Sigma, X, Q, \iota, F, \Delta\rangle$ be an automaton for the rest of this section. For any $i \in \mathbb{N}$, we denote by $Q^{(i)} = \{q^{(i)} \mid q \in Q\}$ and $X^{(i)} = \{x^{(i)} \mid x \in X\}$ the sets of time-stamped predicate symbols and variables, respectively. We also define $Q^{(\leq n)} \stackrel{\text{def}}{=} \{q^{(i)} \mid q \in Q, i \in [n]\}$ and $X^{(\leq n)} \stackrel{\text{def}}{=} \{x^{(i)} \mid x \in X, i \in [n]\}$. For a formula ψ and $i \in \mathbb{N}$, we define $\psi^{(i)} \stackrel{\text{def}}{=} \psi[X^{(i)}/X, Q^{(i)}/Q]$ the formula in which all input variables and state predicates (and only those symbols) are replaced by their time-stamped counterparts. Moreover, we write $q(\mathbf{y})$ for $q(y_1, \ldots, y_{\#(q)})$, when no confusion arises.

Given a sequence of input events $\alpha = a_1 \ldots a_n \in \Sigma^*$, the *path formula* of α is:

$$\Theta(\alpha) \stackrel{\text{def}}{=} \iota^{(0)} \wedge \bigwedge_{i=1}^{n} \bigwedge_{q(\mathbf{y}) \xrightarrow{a_i(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \cdot q^{(i-1)}(\mathbf{y}) \rightarrow \psi^{(i)} \tag{1}$$

The automaton $\mathcal{A}$, to which $\Theta(\alpha)$ refers, will always be clear from the context. To formalize the relation between the low-level configuration-based execution semantics and path formulae, consider a word $w = (a_1, \nu_1) \dots (a_n, \nu_n) \in \Sigma[X]^*$. Any execution $\mathcal{T}$ of $\mathcal{A}$ over w has an associated interpretation $\mathcal{I}_\mathcal{T}$ of time-stamped predicates $Q^{(\leq n)}$:

$\mathcal{I}_\mathcal{T}(q^{(i)}) \stackrel{\text{def}}{=} \{(d_1, \dots, d_{\#(q)}) \mid (q, d_1, \dots, d_{\#(q)})$ labels a node on level i in $\mathcal{T}\}$, $\forall q \in Q\ \forall i \in [n]$

Lemma 1. *Given an automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$, for any word $w = (a_1, \nu_1) \dots (a_n, \nu_n)$, we have $[\![\Theta(w_\Sigma)]\!]^\mu_{w_\mathbb{D}} = \{\mathcal{I}_\mathcal{T} \mid \mathcal{T}$ is an execution of $\mathcal{A}$ over $w\}$.*

Next, we give a logical characterization of acceptance, relative to a given sequence of input events $\alpha \in \Sigma^*$. To this end, we constrain the path formula $\Theta(\alpha)$ by requiring that only final states of $\mathcal{A}$ occur on the last level of the execution. The result is the *acceptance formula* for α:

$$\Upsilon(\alpha) \stackrel{\text{def}}{=} \Theta(\alpha) \wedge \bigwedge_{q \in Q \setminus F} \forall y_1 \dots \forall y_{\#(q)} \,.\, q^{(n)}(\mathbf{y}) \rightarrow \bot \tag{2}$$

The top-level universal quantifiers from a subformula $\forall y_1 \dots \forall y_{\#(q)} \,.\, q^{(i)}(\mathbf{y}) \rightarrow \psi$ of $\Upsilon(\alpha)$ will be referred to as *path quantifiers*, in the following. Notice that path quantifiers are distinct from the transition quantifiers that occur within a formula ψ of a transition rule $q(y_1, \dots, y_{\#(q)}) \xrightarrow{a(X)} \psi$ of $\mathcal{A}$. The relation between the words accepted by $\mathcal{A}$ and the acceptance formula above, is formally captured by the following lemma:

Lemma 2. *Given an automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$, for every word $w \in \Sigma[X]^*$, the following are equivalent:*

1. *there exists an interpretation $\mathcal{I}$ such that $\mathcal{I}, w_\mathbb{D} \models \Upsilon(w_\Sigma)$,*
2. *$w \in \mathcal{L}(\mathcal{A})$.*

As an immediate consequence, one can decide whether $\mathcal{A}$ accepts some word w with a given input sequence $w_\Sigma = \alpha$, by checking whether $\Upsilon(\alpha)$ is satisfiable. However, unlike non-alternating infinite-state models of computation, such as counter automata (nondeterministic programs with integer variables), the satisfiability query for an acceptance (path) formula falls outside of known decidable theories, supported by standard SMT solvers. There are basically two reasons for this, namely (i) the presence of predicate symbols, and (ii) the non-trivial alternation of quantifiers. To understand this point, consider for example, the decidable theory of Presburger arithmetic [22]. Adding even only one monadic predicate symbol to it yields undecidability in the presence of non-trivial quantifier alternation [9]. On the other hand, the quantifier-free fragment of Presburger arithmetic extended with uninterpreted function symbols is decidable, by a Nelson-Oppen style congruence closure argument [20].

To tackle the problem of deciding satisfiability of $\Upsilon(\alpha)$ formulae, we start from the observation that their form is rather particular, which allows the elimination of path quantifiers and uninterpreted predicate symbols, by a couple of satisfiability-preserving transformations. The result of applying these transformations is a formula with no predicate symbols, whose only quantifiers are those introduced by the transition rules of the automaton. Next, in §3 we shall assume moreover that the first order theory of the data sort $\mathbb{D}$ (without uninterpreted predicate symbols) has quantifier elimination, providing thus an effective decision procedure.

For the time being, let us formally define the elimination of transition quantifiers and predicate symbols. Let $\alpha = a_1 \dots a_n$ be a given sequence of input events and let α_i be

the prefix $a_1 \ldots a_i$ of α, for $i \in [n]$, where $\alpha_0 = \epsilon$. We consider the sequence of formulae $\widehat{\Theta}(\alpha_0), \ldots, \widehat{\Theta}(\alpha_n)$ defined as $\widehat{\Theta}(\alpha_0) \stackrel{\text{def}}{=} \iota^{(0)}$ and, for all $i \in [1,n]$, let $\widehat{\Theta}(\alpha_i)$ be the conjunction of $\widehat{\Theta}(\alpha_{i-1})$ with all formulae $q^{(i-1)}(t_1, \ldots, t_{\#(q)}) \rightarrow \psi^{(i)}[t_1/y_1, \ldots, t_{\#(q)}/y_{\#(q)}]$, such that $q^{(i-1)}(t_1, \ldots, t_{\#(q)})$ occurs in $\widehat{\Theta}(\alpha_{i-1})$, for some terms $t_1, \ldots, t_{\#(q)}$. Next, we write $\widehat{\Upsilon}(\alpha)$ for the conjunction of $\widehat{\Theta}(\alpha_n)$ with all $q^{(n)}(t_1, \ldots, t_{\#(q)}) \rightarrow \bot$, such that $q^{(n)}(t_1, \ldots, t_{\#(q)})$ occurs in $\widehat{\Theta}(\alpha_n)$, for some $q \in Q \setminus F$. Note that $\widehat{\Upsilon}(\alpha)$ contains no path quantifiers, as required. On the other hand, the scope of the transition quantifiers in $\widehat{\Upsilon}(\alpha)$ exceeds the right-hand side formulae from the transition rules, as shown by the following example.

Example 2. Consider the automaton $\mathcal{A} = \langle \{a_1, a_2\}, \{x\}, \{q, q_f\}, \iota, \{q_f\}, \Delta \rangle$, where:

$$\iota = \exists z \,.\, z \geq 0 \wedge q(z)$$
$$\Delta = \{q(y) \xrightarrow{a_1(x)} x \geq 0 \wedge \forall z \,.\, z \leq y \rightarrow q(x+z),\ q(y) \xrightarrow{a_2(x)} y < 0 \wedge q_f(x+y)\}$$

For the input event sequence $\alpha = a_1 a_2$, the acceptance formula is:

$$\begin{array}{l} \Upsilon(\alpha) = \exists z_1 \,.\, z_1 \geq 0 \wedge q^{(0)}(z_1) \wedge \\ \qquad \forall y \,.\, q^{(0)}(y) \rightarrow [x^{(1)} \geq 0 \wedge \forall z_2 \,.\, z_2 \geq y \rightarrow q^{(1)}(x^{(1)} + z_2)] \wedge \\ \qquad \forall y \,.\, q^{(1)}(y) \rightarrow [y < 0 \wedge {q_f}^{(2)}(x^{(2)} + y)] \end{array}$$

The result of eliminating the path quantifiers, in prenex normal form, is shown below:

$$\begin{array}{l} \widehat{\Upsilon}(\alpha) = \exists z_1 \forall z_2 \,.\, z_1 \geq 0 \wedge q^{(0)}(z_1) \wedge \\ \qquad [q^{(0)}(z_1) \rightarrow x^{(1)} \geq 0 \wedge (z_2 \geq z_1 \rightarrow q^{(1)}(x^{(1)} + z_2))] \wedge \\ \qquad [q^{(1)}(x^{(1)} + z_2) \rightarrow x^{(1)} + z_2 < 0 \wedge {q_f}^{(2)}(x^{(2)} + x^{(1)} + z_2)] \end{array}$$

Notice that the transition quantifiers $\exists z_1$ and $\forall z_2$ from $\Upsilon(\alpha)$ range now over the entire formula $\widehat{\Upsilon}(\alpha)$. ■

Lemma 3. *For any input event sequence $\alpha = a_1 \ldots a_n$ and each valuation $\nu : X^{(\leq n)} \rightarrow \mathbb{D}$, the following hold, for every interpretation $\mathcal{I}$:*

1. *if $\mathcal{I}, \nu \models \Upsilon(\alpha)$ then $\mathcal{I}, \nu \models \widehat{\Upsilon}(\alpha)$, and*
2. *if $\mathcal{I}, \nu \models \widehat{\Upsilon}(\alpha)$ there exists an interpretation $\mathcal{J} \subseteq \mathcal{I}$ such that $\mathcal{J}, \nu \models \Upsilon(\alpha)$.*

Further, we eliminate the predicate atoms from $\widehat{\Upsilon}(\alpha)$, by considering the sequence of formulae $\overline{\Theta}(\alpha_0) \stackrel{\text{def}}{=} \iota^{(0)}$ and $\overline{\Theta}(\alpha_i)$ is obtained by substituting each predicate atom $q^{(i-1)}(t_1, \ldots, t_{\#(q)})$ in $\overline{\Theta}(\alpha_{i-1})$ by $\psi^{(i)}[t_1/y_1, \ldots, t_{\#(q)}/y_{\#(q)}]$, where $q(\mathbf{y}) \xrightarrow{a_i(X)} \psi \in \Delta$, for all $i \in [1,n]$. We write $\overline{\Upsilon}(\alpha)$ for the formula obtained by replacing, in $\overline{\Theta}(\alpha)$, each occurrence of a predicate $q^{(n)}$, such that $q \in Q \setminus F$ (resp. $q \in F$), by $\bot$ (resp. $\top$).

Example 3 (Contd. from Example 2). The result of the elimination of predicate atoms from the acceptance formula in Example 2 is shown below:

$$\overline{\Upsilon}(\alpha) = \exists z_1 \forall z_2 \,.\, z_1 \geq 0 \wedge [x^{(1)} \geq 0 \wedge (z_2 \geq z_1 \rightarrow x^{(1)} + z_2 < 0)]$$

Since this formula is unsatisfiable, by Lemma 5 below, no word w with input event sequence $w_\Sigma = a_1 a_2$ is accepted by the automaton $\mathcal{A}$ from Example 2. ■

At this point, we prove the formal relation between the satisfiability of the formulae $\widehat{\Upsilon}(\alpha)$ and $\overline{\Upsilon}(\alpha)$. Since there are no occurrences of predicates in $\overline{\Upsilon}(\alpha)$, for each valuation $\nu : X^{(\leq n)} \rightarrow \mathbb{D}$, there exists an interpretation $\mathcal{I}$ such that $\mathcal{I}, \nu \models \overline{\Upsilon}(\alpha)$ if and only if $\mathcal{J}, \nu \models \overline{\Upsilon}(\alpha)$, for every interpretation $\mathcal{J}$. In this case we omit $\mathcal{I}$ and simply write $\nu \models \overline{\Upsilon}(\alpha)$.

Lemma 4. *For any input event sequence $\alpha = a_1 \dots a_n$ and each valuation $\nu : X^{(\leq n)} \to \mathbb{D}$, there exists a valuation $\mathcal{I}$ such that $\mathcal{I}, \nu \models \widehat{\Upsilon}(\alpha)$ if and only if $\nu \models \overline{\Upsilon}(\alpha)$.*

Finally, we define the acceptance of a word with a given input event sequence by means of a quantifier-free formula in which no predicate atom occurs.

Lemma 5. *Given an automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$, for every word $w \in \Sigma[X]^*$, we have $w_{\mathbb{D}} \models \overline{\Upsilon}(w_\Sigma)$ if and only if $w \in \mathcal{L}(\mathcal{A})$.*

2.2 Boolean Closure of First Order Alternating Automata

Given a positive formula ϕ, we define the *dual* formula $\phi^\sim$ recursively as follows:

$$(\phi_1 \vee \phi_2)^\sim \stackrel{\text{def}}{=} \phi_1{}^\sim \wedge \phi_2{}^\sim \qquad (\phi_1 \wedge \phi_2)^\sim \stackrel{\text{def}}{=} \phi_1{}^\sim \vee \phi_2{}^\sim \qquad (t = s)^\sim \stackrel{\text{def}}{=} t \neq s$$
$$(\exists x \,.\, \phi_1)^\sim \stackrel{\text{def}}{=} \forall x \,.\, \phi_1{}^\sim \qquad (\forall x \,.\, \phi_1)^\sim \stackrel{\text{def}}{=} \exists x \,.\, \phi_1{}^\sim \qquad (t \neq s)^\sim \stackrel{\text{def}}{=} t = s$$
$$q(x_1, \dots, x_{\#(q)})^\sim \stackrel{\text{def}}{=} q(x_1, \dots, x_{\#(q)})$$

The following theorem shows closure of automata under all boolean operations. Note that it is sufficient to show closure under intersection and negation because $\mathcal{L}(\mathcal{A}_1) \cup \mathcal{L}(\mathcal{A}_2)$ is the complement of the language $\mathcal{L}^c(\mathcal{A}_1) \cap \mathcal{L}^c(\mathcal{A}_2)$, for any two automata $\mathcal{A}_1$ and $\mathcal{A}_2$ with the same input event alphabet and set of input variables.

Theorem 1. *Given automata $\mathcal{A}_i = \langle \Sigma, X, Q_i, \iota_i, F_i, \Delta_i \rangle$, for $i = 1, 2$, such that $Q_1 \cap Q_2 = \emptyset$, the following hold:*

1. *$\mathcal{L}(\mathcal{A}_\cap) = \mathcal{L}(\mathcal{A}_1) \cap \mathcal{L}(\mathcal{A}_2)$, where $\mathcal{A}_\cap = \langle \Sigma, X, Q_1 \cup Q_2, \iota_1 \wedge \iota_2, F_1 \cup F_2, \Delta_1 \cup \Delta_2 \rangle$,*
2. *$\mathcal{L}(\overline{\mathcal{A}_i}) = \Sigma[X]^* \setminus \mathcal{L}(\mathcal{A}_i)$, where $\overline{\mathcal{A}_i} = \langle \Sigma, X, Q_i, \iota^\sim, Q_i \setminus F_i, \Delta_i^\sim \rangle$ and, for $i = 1, 2$:*

$$\Delta_i^\sim = \{ q(\mathbf{y}) \xrightarrow{a(X)} \psi^\sim \mid q(\mathbf{y}) \xrightarrow{a(X)} \psi \in \Delta_i \} \ .$$

Moreover, $|\mathcal{A}_\cap| = O(|\mathcal{A}_1| + |\mathcal{A}_2|)$ and $|\overline{\mathcal{A}_i}| = O(|\mathcal{A}_i|)$, for all $i = 1, 2$.

Proof sketch. (1) The proof for $\mathcal{A}_\cap$ is similar to the standard proof for the intersection of propositional alternating automata. (2) Let $w \in \Sigma[X]^*$ be a word. We denote by $\Upsilon_{\mathcal{A}_1}(w_\Sigma)$ and $\overline{\Upsilon}_{\mathcal{A}_1}(w_\Sigma)$ [resp. $\Upsilon_{\overline{\mathcal{A}}_1}(w_\Sigma)$ and $\overline{\Upsilon}_{\overline{\mathcal{A}}_1}(w_\Sigma)$] the formulae $\Upsilon(w_\Sigma)$ and $\overline{\Upsilon}(w_\Sigma)$ for $\mathcal{A}_1$ and $\overline{\mathcal{A}}_1$, respectively. It is enough to show that $\overline{\Upsilon}_{\overline{\mathcal{A}}_1}(w_\Sigma) = \neg \overline{\Upsilon}_{\mathcal{A}_1}(w_\Sigma)$ and apply Lemma 5 to prove that $w \in \mathcal{L}(\mathcal{A}_1) \Leftrightarrow w \notin \mathcal{L}(\overline{\mathcal{A}}_1)$. Since the choice of w was arbitrary, this proves $\mathcal{L}(\overline{\mathcal{A}}_1) = \Sigma[X]^* \setminus \mathcal{L}(\mathcal{A}_1)$. The proof is by induction on the number of predicate atoms in $\Upsilon_{\mathcal{A}_1}(w_\Sigma)$ that are replaced during the generation of $\overline{\Upsilon}_{\mathcal{A}_1}(w_\Sigma)$ and relies on the following fact, itself proved by induction on the structure of ϕ:

Fact 1 *Let ϕ be a positive first order formula and let $q(t_1, \dots, t_{\#(q)})$ be the only occurrence of a predicate symbol within ϕ. Then, for any formula ψ, we have the equivalence:*
$\neg\phi[\psi[t_1/y_1, \dots, t_{\#(q)}/y_{\#(q)}]/q(t_1, \dots, t_{\#(q)})] \equiv \phi^\sim[\neg\psi[t_1/y_1, \dots, t_{\#(q)}/y_{\#(q)}]/q(t_1, \dots, t_{\#(q)})]$

3 The Emptiness Problem

The emptiness problem is undecidable even for automata with predicates of arity two, whose transition rules use only equalities and disequalities, having no transition quantifiers [5]. Since even such simple classes of alternating automata have no general decision procedure for emptiness, we use an abstraction-refinement semi-algorithm based on *lazy annotation* [18,19].

In a nutshell, a lazy annotation procedure systematically explores the set of finite input event sequences searching for an accepting execution. For an input sequence, if the path formula is satisfiable, we compute a word in the language of the automaton, from the model of the path formula. Otherwise, i.e. the sequence is *spurious*, the search backtracks and each position in the sequence is annotated with a tuple of interpolants, that marks the entire sequence as infeasible. The semi-algorithm uses moreover a coverage relation between sequences, ensuring that the continuations of already covered sequences are never explored. Sometimes this coverage relation provides a sound termination argument, in case when the automaton is empty.

We check emptiness of first order alternating automata using a version of the IMPACT lazy annotation semi-algorithm [18]. An analogous procedure is given in [12], for a simpler model of alternating automata, that uses only predicates or arity zero (propositional variables) and no transition quantifiers. For simplicity, we defer the pseudocode of the semi-algorithm to Appendix A and give here several high-level definitions.

For two input event sequences $\alpha, \beta \in \Sigma^*$, we say that α is a prefix of β, written $\alpha \preceq \beta$, if $\alpha = \beta\gamma$ for some sequence $\gamma \in \Sigma^*$. A set S of sequences is *prefix-closed* if for each $\alpha \in S$, if $\beta \preceq \alpha$ then $\beta \in S$, and *complete* if for each $\alpha \in S$, there exists $a \in \Sigma$ such that $\alpha a \in S$ if and only if $\alpha b \in S$ for all $b \in \Sigma$. A prefix-closed set is the backbone of a tree whose edges are labeled with input events. If the set is, moreover, complete, then every node of the tree has either zero successors, in which case it is called a *leaf*, or it has a successor edge labeled with a for each input event $a \in \Sigma$.

Definition 2. *An* unfolding *of an automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$ is a finite partial mapping $U : \Sigma^* \rightharpoonup_{fin} \mathsf{Form}^+(Q, \emptyset)$, whose domain* $\mathrm{dom}(U)$ *is a finite prefix-closed complete set, such that $U(\epsilon) = \iota$, and for each sequence $\alpha a \in \mathrm{dom}(U)$, such that $\alpha \in \Sigma^*$ and $a \in \Sigma$:*

$$U(\alpha)^{(0)} \wedge \bigwedge_{q(\mathbf{y}) \xrightarrow{a(X)} \psi} \forall y_1 \ldots \forall y_{\#q} \,.\, q^{(0)}(\mathbf{y}) \rightarrow \psi^{(1)} \models U(\alpha a)^{(1)}$$

A path α is safe *in U if and only if $U(\alpha) \wedge \bigwedge_{q \in Q \setminus F} \forall y_1 \ldots \forall_{y_{\#(q)}} \,.\, q(\mathbf{y}) \rightarrow \bot$ is unsatisfiable. The unfolding U is safe if and only if every path in* $\mathrm{dom}(U)$ *is safe in U.*

Lazy annotation semi-algorithms [18,19] build unfoldings of automata trying to discover counterexamples for emptiness. If the automaton $\mathcal{A}$ in question is non-empty, a systematic enumeration of the input event sequences[3] from Σ^* will suffice to discover a word $w \in \mathcal{L}(\mathcal{A})$, provided that the first order theory of the data domain $\mathbb{D}$ is decidable (Lemma 2). However, if $\mathcal{L}(\mathcal{A}) = \emptyset$, the enumeration of input event sequences may, in principle, run forever. The typical way of fighting this divergence problem is to define a *coverage* relation between the nodes of the unfolding tree.

Definition 3. *Given an unfolding U of an automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$ a node $\alpha \in \mathrm{dom}(U)$ is* covered *by another node $\beta \in \mathrm{dom}(U)$, denoted $\alpha \sqsubseteq \beta$, if and only if there exists a node $\alpha' \preceq \alpha$ such that $U(\alpha') \models U(\beta)$. Moreover, U is* closed *if and only if every leaf from* $\mathrm{dom}(U)$ *is covered by an uncovered node.*

A lazy annotation semi-algorithm will stop and report emptiness provided that it succeeds in building a closed and safe unfolding of the automaton. Notice that, by Definition 3, for any three nodes of an unfolding U, say $\alpha, \beta, \gamma \in \mathrm{dom}(U)$, if $\alpha \prec \beta$ and $\alpha \sqsubseteq \gamma$, then $\beta \sqsubseteq \gamma$ as well. As we show next (Theorem 2), there is no need to expand

[3] For instance, using breadth-first search.

covered nodes, because, intuitively, there exists a word $w \in \mathcal{L}(\mathcal{A})$ such that $\alpha \preceq w_\Sigma$ and $\alpha \sqsubseteq \gamma$ only if there exists another word $u \in \mathcal{L}(\mathcal{A})$ such that $\gamma \preceq u_\Sigma$. Hence, exploring only those input event sequences that are continuations of γ (and ignoring those of α) suffices in order to find a counterexample for emptiness, if one exists.

An unfolding node $\alpha \in \mathrm{dom}(U)$ is said to be *spurious* if and only if $\Upsilon(\alpha)$ is unsatisfiable. In this case, we change (refine) the labels of (some of the) prefixes of α (and that of α), such that $U(\alpha)$ becomes $\bot$, thus indicating that there is no real execution of the automaton along that input event sequence. As a result of the change of labels, if a node $\gamma \preceq \alpha$ used to cover another node from $\mathrm{dom}(U)$, it might not cover it with the new label. Therefore, the coverage relation has to be recomputed after each refinement of the labeling. The semi-algorithm stops when (and if) a safe complete unfolding has been found. For a detailed presentation of the emptiness procedure, we refer to Appendix A.

Theorem 2. *If an automaton $\mathcal{A}$ has a nonempty safe closed unfolding then $\mathcal{L}(A) = \emptyset$.*

As mentioned above, we check emptiness of first order alternating automata using a semi-algorithm previously used to check emptiness of a simpler model of alternating automata, which uses propositional variables for control states and whose transition rules have no quantifiers [12]. The higher complexity of the automata model considered here, manifests itself within the interpolant generation procedure, used to refine the labeling of the unfolding. We discuss generation of interpolants in the next section.

4 Interpolant Generation

Typically, when checking the unreachability of a set of program configurations, the interpolants used to annotate the unfolded control structure are assertions about the values of the program variables in a given control state, at a certain step of an execution [18]. Because we consider alternating computation trees (forests), we must distinguish between (i) locality of interpolants w.r.t. a given control state (control locality) and (ii) locality w.r.t. a given time stamp (time locality). In logical terms, *control-local* interpolants are formulae involving a single predicate symbol, whereas *time-local* interpolants involve only predicates $q^{(i)}$ and variables $x^{(i)}$, for a single $i \geq 0$.

Remark When considering alternating executions, control-local interpolants are not always enough to prove emptiness, because of the synchronization of several branches of the computation on the same input word. Consider, for instance, the automaton from Example 1, started in an initial configuration $q_0(0)$, on an input word $(a, \nu_1) \ldots (a, \nu_n)$, such that $\nu_i(x) = k_i$, for all $i \in [1, n]$, the automaton executes as follows:

$$\{(q_0, 0)\} \xrightarrow{(a,\nu_1)} \{(q_1, k_1), (q_2, -k_1)\} \ldots \xrightarrow{(a,\nu_n)} \{(q_1, \sum_{i=1}^{n} k_i), (q_2, -\sum_{i=1}^{n} k_i)\}$$

An overapproximation of the set of cubes generated after one or more steps is defined by the formula $\exists x_1 \exists x_2 \,.\, q_1(x_1) \wedge q_2(x_2) \wedge x_1 + x_2 \geq 0$. Note that a control-local formula using one occurrence of a predicate would give a too rough overapproximation of this set, unable to prove the emptiness of the automaton. This is because any formula with a single occurrence of an atom of the form $q(x)$ would lose the constraint $x_1 + x_2 \geq 0$ between the values occurring at the same level, on both branches of the execution. ■

First, let us give the formal definition of the class of interpolants we shall work with. Given a formula ϕ, the *vocabulary* of ϕ, denoted $\mathrm{V}(\phi)$ is the set of predicate symbols $q \in Q^{(i)}$ and variables $x \in X^{(i)}$, occurring in ϕ, for some $i \geq 0$. For a term t, its vocabulary

$\mathrm{V}(t)$ is the set of variables that occur in t. Observe that quantified variables and the interpreted function symbols of the data theory[4] do not belong to the vocabulary of a formula. By $\mathrm{P}^+(\phi)$ [$\mathrm{P}^-(\phi)$] we denote the set of predicate symbols that occur in ϕ under an even [odd] number of negations.

Definition 4 ([17]). *Given formulae ϕ and ψ such that $\phi \wedge \psi$ is unsatisfiable, a* Lyndon interpolant *is a formula I such that $\phi \models I$, the formula $I \wedge \psi$ is unsatisfiable, $\mathrm{V}(I) \subseteq \mathrm{V}(\phi) \cap \mathrm{V}(\psi)$, $\mathrm{P}^+(I) \subseteq \mathrm{P}^+(\phi) \cap \mathrm{P}^+(\psi)$ and $\mathrm{P}^-(I) \subseteq \mathrm{P}^-(\phi) \cap \mathrm{P}^-(\psi)$.*

In the rest of this section, fix an automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$. Due to the above remark, none of the interpolants considered will be control-local and we shall use the term *local* to denote time-local interpolants, with no free variables. The following definition generalizes interpolants from unsatisfiable conjunctions to input sequences:

Definition 5. *Given a non-empty sequence of input events $\alpha = a_1 \ldots a_n \in \Sigma^*$, a* generalized Lyndon interpolant (GLI) *is a sequence $(I_0, \ldots, I_n)$ of formulae such that, for all $k \in [n-1]$, the following hold:*

1. $\mathrm{P}^-(I_k) = \emptyset$,
2. $\iota^{(0)} \models I_0$ *and* $I_k \wedge \Big(\bigwedge_{q(\mathbf{y}) \xrightarrow{a_i(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(k)}(\mathbf{y}) \rightarrow \psi^{(k+1)} \Big) \models I_{k+1}$,
3. $I_n \wedge \bigwedge_{q \in Q \setminus F} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q(\mathbf{y}) \rightarrow \bot$ *is unsatisfiable.*

Moreover, the GLI is local *if and only if $\mathrm{V}(I_k) \subseteq Q^{(k)}$, for all $k \in [n]$.*

The following proposition states the existence of local GLI for the theories in which Lyndon's Interpolation Theorem holds.

Proposition 1. *If there exists a Lyndon interpolant for any two formulae ϕ and ψ, in the first order theory of data with uninterpreted predicate symbols, such that $\phi \wedge \psi$ is unsatisfiable, then any sequence of input events $\alpha = a_1 \ldots a_n \in \Sigma^*$, such that $\Upsilon(\alpha)$ is unsatisfiable, has a local GLI $(I_0, \ldots, I_n)$.*

Proof. By definition, $\Upsilon(\alpha)$ is the formula:

$$\iota^{(0)} \wedge \bigwedge_{i=1}^{n} \underbrace{\bigwedge_{q(\mathbf{y}) \xrightarrow{a_i(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(i-1)}(\mathbf{y}) \rightarrow \psi^{(i)}}_{\varphi_i} \wedge \underbrace{\bigwedge_{q \in Q \setminus F} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(n)}(\mathbf{y}) \rightarrow \bot}_{\phi}$$

Observe that $\mathrm{V}(\iota^{(0)}) \subseteq Q^{(0)}$, $\mathrm{V}(\varphi_i) \subseteq Q^{(i-1)} \cup Q^{(i)} \cup X^{(i)}$, for all $i \in [1, n]$, and $\mathrm{V}(\phi) \subseteq Q^{(n)}$. We apply Lyndon's Interpolation Theorem for the formulae $\iota^{(0)}$ and $\bigwedge_{i=1}^{n} \varphi_i \wedge \phi$ and obtain a formula I_0, such that $\iota^{(0)} \models I_0$, $I_0 \wedge \bigwedge_{i=1}^{n} \varphi_i \wedge \phi$ is unsatisfiable, $\mathrm{V}(I_0) \subseteq \mathrm{V}(\iota^{(0)}) \cap (\bigcup_{i=1}^{n} \mathrm{V}(\varphi_i) \cup \mathrm{V}(\phi)) \subseteq Q^{(0)}$ and $\mathrm{P}^-(I_0) \subseteq \mathrm{P}^-(\iota^{(0)}) \cap (\bigcup_{i=1}^{n} \mathrm{P}^-(\varphi) \cup \mathrm{P}^-(\phi)) = \emptyset$. Repeating the reasoning for the formulae $I_0 \wedge \varphi_1$ and $\bigwedge_{i=2}^{n} \varphi_i \wedge \phi$, we obtain I_1, such that $I_0 \wedge \varphi_1 \models I_1$, $I_1 \wedge \bigwedge_{i=2}^{n} \varphi_i \wedge \phi$ is unsatisfiable, $\mathrm{V}(I_1) \subseteq (\mathrm{V}(I_0) \cup \mathrm{V}(\varphi_1)) \cap (\bigcup_{i=2}^{n} \mathrm{V}(\varphi_i) \cup \mathrm{V}(\phi)) \subseteq Q^{(1)}$ and $\mathrm{P}^-(I_1) \subseteq (\mathrm{P}^-(I_0) \cup \mathrm{P}^-(\varphi_1)) \cap (\bigcup_{i=2}^{n} \mathrm{P}^-(\varphi_i) \cup \mathrm{P}^-(\phi)) = \emptyset$. Continuing in this way, we obtain formulae $I_0, I_1, \ldots, I_n$ as required. □

A problematic point of the above proposition is that the existence of Lyndon interpolants (Definition 4) is proved in principle, but the proof is non-constructive. In other words, the proof of Proposition 1 does not yield an algorithm for computing GLIs, for

[4] E.g., the arithmetic operators of addition and multiplication, when $\mathbb{D}$ is the set of integers.

the following reason. Building an interpolant for an unsatisfiable conjunction of formulae $\phi \wedge \psi$ is typically the job of the decision procedure that proves the unsatisfiability and, in general, there is no such procedure, when ϕ and ψ contain predicates and have non-trivial quantifier alternation. In this case, some provers use instantiation heuristics for the universal quantifiers that are sufficient for proving unsatisfiability, however these heuristics are not always suitable for interpolant generation. Consequently, from now on, we assume the existence of an effective Lyndon interpolation procedure only for decidable theories, such as the quantifier-free linear (integer) arithmetic with uninterpreted functions (UFLIA, UFLRA, etc.) [24].

This is where the predicate-free path formulae (defined in §2.1) come into play. Recall that, for a given event sequence α, the automaton $\mathcal{A}$ accepts a word w such that $w_\Sigma = \alpha$ if and only if $\overline{\Upsilon}(\alpha)$ is satisfiable (Lemma 5). Assuming further that the equality and interpreted predicates (e.g. inequalities for integers) atoms from the transition rules of $\mathcal{A}$ belong to a decidable first order theory, such as Presburger arithmetic, Lemma 5 gives us an effective way of checking emptiness of $\mathcal{A}$, relative to a given event sequence. However, this method does not cope well with lazy annotation, because there is no way to extract, from the unsatisfiability proof of $\overline{\Upsilon}(\alpha)$, the interpolants needed to annotate α. This is because (I) the formula $\overline{\Upsilon}(\alpha)$, obtained by repeated substitutions loses track of the steps of the execution, and (II) quantifiers that occur nested in $\overline{\Upsilon}(\alpha)$ make it difficult to write $\overline{\Upsilon}(\alpha)$ as an unsatisfiable quantifier-free conjunction of formulae from which interpolants are extracted (Definition 4).

The solution we adopt for the first issue (I) consists in partially recovering the time-stamped structure of the acceptance formula $\Upsilon(\alpha)$ using the formula $\widehat{\Upsilon}(\alpha)$, in which only transition quantifiers occur. The second issue (II) is solved under the additional assuption that the theory of the data domain $\mathbb{D}$ has *witness-producing quantifier elimination*. More precisely, we assume that, for each formula $\exists x \,.\, \phi(x)$, there exists an effectively computable term τ, in which x does not occur, such that $\exists x \,.\, \phi$ and $\phi[\tau/x]$ are equisatisfiable. These terms, called *witness terms* in the following, are actual definitions of the Skolem function symbols from the following folklore theorem:

Theorem 3 ([3]). *Given $Q_1 x_1 \ldots Q_n x_n \,.\, \phi$ a first order sentence, where $Q_1, \ldots, Q_n \in \{\exists, \forall\}$ and ϕ is quantifier-free, let $\eta_i \stackrel{\text{def}}{=} f_i(y_1, \ldots, y_{k_i})$ if $Q_i = \forall$ and $\eta_i \stackrel{\text{def}}{=} x_i$ if $Q_i = \exists$, where f_i is a fresh function symbol and $\{y_1, \ldots, y_{k_i}\} = \{x_j \mid j < i,\ Q_j = \exists\}$. Then the entailment $Q_1 x_1 \ldots Q_n x_n \,.\, \phi \models \phi[\eta_1/x_1, \ldots, \eta_n/x_n]$ holds.*

Proof. See [3, Theorem 2.1.8] and [3, Lemma 2.1.9]. □

Examples of witness-producing quantifier elimination procedures can be found in the literature for e.g. linear integer (real) arithmetic (LIA,LRA), Presburger arithmetic and boolean algebra of sets and Presburger cardinality constraints (BAPA) [16].

Under the assumption that witness terms can be effectively built, we describe the generation of a non-local GLI for a given input event sequence $\alpha = a_1 \ldots a_n$. First, we generate successively the acceptance formula $\Upsilon(\alpha)$ and its equisatisfiable forms $\widehat{\Upsilon}(\alpha) = Q_1 x_1 \ldots Q_m x_m \,.\, \widehat{\Phi}$ and $\overline{\Upsilon}(\alpha) = Q_1 x_1 \ldots Q_m x_m \,.\, \overline{\Phi}$, both written in prenex form, with matrices $\widehat{\Phi}$ and $\overline{\Phi}$, respectively. Because we assumed that the first order theory of $\mathbb{D}$ has quantifier elimination, the satisfiability problem for $\overline{\Upsilon}(\alpha)$ is decidable. If $\overline{\Upsilon}(\alpha)$ is satisfiable, we build a counterexample for emptiness w such that $w_\Sigma = \alpha$ and $w_\mathbb{D}$ is a satisfying assignment for $\overline{\Upsilon}(\alpha)$. Otherwise, $\overline{\Upsilon}(\alpha)$ is unsatisfiable and there exist witness

terms $\tau_{i_1} \ldots \tau_{i_\ell}$, where $\{i_1, \ldots, i_\ell\} = \{j \in [1,m] \mid Q_j = \forall\}$, such that $\overline{\Phi}[\tau_{i_1}/x_{i_1}, \ldots, \tau_{i_\ell}/x_{i_\ell}]$ is unsatisfiable (Theorem 3). Then it turns out that the formula $\widehat{\Phi}[\tau_{i_1}/x_{i_1}, \ldots, \tau_{i_\ell}/x_{i_\ell}]$, obtained analogously from the matrix of $\widehat{\Upsilon}(\alpha)$, is unsatisfiable as well (Lemma 6 below). Because this latter formula is structured as a conjunction of formulae $\iota^{(0)} \wedge \phi_1 \ldots \wedge \phi_n \wedge \psi$, where $\mathrm{V}(\phi_k) \cap Q^{(\leq n)} \subseteq Q^{(k-1)} \cup Q^{(k)}$ and $\mathrm{V}(\psi) \cap Q^{(\leq n)} \subseteq Q^{(n)}$, it is now possible to use an existing interpolation procedure for the quantifier-free theory of $\mathbb{D}$, extended with uninterpreted function symbols, to compute a (not necessarily local) GLI $(I_0, \ldots, I_n)$ such that $\mathrm{V}(I_k) \cap Q^{(\leq n)} \subseteq Q^{(k)}$, for all $k \in [n]$.

Example 4 (Contd. from Examples 2 and 3). The formula $\overline{\Upsilon}(\alpha)$ (Example 3) is unsatisfiable and let $\tau_2 \stackrel{\text{def}}{=} z_1$ be the witness term for the universally quantified variable z_2. Replacing z_2 with τ_2 (z_1) in the matrix of $\widehat{\Upsilon}(\alpha)$ (Example 2) yields the unsatisfiable conjunction below, obtained after trivial simplifications:

$$[z_1 \geq 0 \wedge q^{(0)}(z_1)] \wedge [q^{(0)}(z_1) \rightarrow x^{(1)} \geq 0 \wedge q^{(1)}(x^{(1)} + z_1)] \wedge [q^{(1)}(x^{(1)} + z_1) \rightarrow x^{(1)} + z_1 < 0 \wedge {q_f}^{(2)}(x^{(2)} + x^{(1)} + z_1)]$$

A non-local GLI for the above conjunction is the sequence of formulae:

$$(q^{(0)}(z_1) \wedge z_1 \geq 0,\ x^{(1)} \geq 0 \wedge q^{(1)}(x^{(1)} + z_1) \wedge z_1 \geq 0,\ \bot) \qquad \blacksquare$$

We formalize and prove the correctness for the above construction of non-local GLI. A function $\xi : \mathbb{N} \rightarrow \mathbb{N}$ is *monotonic* iff for each $n < m$ we have $\xi(n) \leq \xi(m)$ and *finite-range* iff for each $n \in \mathbb{N}$ the set $\{m \mid \xi(m) = n\}$ is finite. If ξ is finite-range, we denote by $\xi^{-1}_{\max}(n) \in \mathbb{N}$ the maximal value m such that $\xi(m) = n$.

Lemma 6. *Given a non-empty input event sequence $\alpha = a_1 \ldots a_n \in \Sigma^*$, such that $\Upsilon(\alpha)$ is unsatisfiable, let $Q_1 x_1 \ldots Q_m x_m \,.\, \widehat{\Phi}$ be a prenex form of $\widehat{\Upsilon}(\alpha)$ and let $\xi : [1,m] \rightarrow [n]$ be a monotonic function mapping each transition quantifier to the minimal index from the sequence $\widehat{\Theta}(\alpha_0), \ldots, \widehat{\Theta}(\alpha_n)$ where it occurs. Then one can effectively build:*

1. *witness terms $\tau_{i_1}, \ldots, \tau_{i_\ell}$, where $\{i_1, \ldots, i_\ell\} = \{j \in [1,m] \mid Q_j = \forall\}$ and $\mathrm{V}(\tau_{i_j}) \subseteq X^{(\leq \xi(i_j))} \cup \{x_k \mid k < i_j, Q_k = \exists\}$, $\forall j \in [1,\ell]$ such that $\widehat{\Phi}[\tau_{i_1}/x_{i_1}, \ldots, \tau_{i_\ell}/x_{i_\ell}]$ is unsatisfiable, and*
2. *a GLI $(I_0, \ldots, I_n)$ for α, such that $\mathrm{V}(I_k) \subseteq Q^{(k)} \cup X^{(\leq k)} \cup \{x_j \mid j < \xi^{-1}_{\max}(k),\ Q_j = \exists\}$, for all $k \in [n]$.*

Consequently, under two assumptions about the first order theory of the data domain, namely (i) witness-producing quantifier elimination, and (ii) Lyndon interpolation for the quantifier-free fragment with uninterpreted functions, we developped a generic method that produces GLIs for unfeasible input event sequences. Moreover, each formula I_k in the interpolant refers only to the current predicate symbols $Q^{(I_k)}$, the current and past input variables $X^{(\leq k)}$ and the existentially quantified transition variables introduced at the previous steps $\{x_j \mid j < \xi^{-1}_{\max}(k), Q_j = \exists\}$. The remaining questions are how to use these GLIs to label the sequences in the unfolding of an automaton (Definition 2) and compute coverage (Definition 3) between nodes of the unfolding.

4.1 Unfolding with Non-local Interpolants

As required by Definition 2, the unfolding U of an automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$ is labeled by formulae $U(\alpha) \in \mathsf{Form}^+(Q, \emptyset)$, with no free symbols, other than predicate

symbols, such that the labeling is compatible with the transition relation of the automaton. Each newly expanded input sequence of $\mathcal{A}$ is initially labeled with $\top$ and the labels are refined using GLIs computed from proofs of spuriousness. The following lemma describes the refinement of the labeling of an input sequence by a non-local GLI:

Lemma 7. *Let U be an unfolding of an automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$ such that $\alpha = a_1 \dots a_n \in \mathrm{dom}(U)$ and $(I_0, \dots, I_n)$ is a GLI for α. Then the mapping $U' : \mathrm{dom}(U) \to \mathsf{Form}^+(Q, \emptyset)$ is an unfolding of $\mathcal{A}$, where:*

- *$U'(\alpha_k) = U(\alpha_k) \wedge J_k$, for all $k \in [n]$, where J_k is the formula obtained from I_k by removing the time stamp of each predicate symbol $q^{(k)}$ and existentially quantifying each free variable in $I_{,k}$,*
- *$U'(\beta) = U(\beta)$ if $\beta \in \mathrm{dom}(U)$ and $\beta \not\preceq \alpha$,*

Moreover, α is safe in U'.

Observe that, by Lemma 6 (2), the set of free variables of a GLI formula I_k consists of (i) variables $X^{(\leq k)}$ keeping track of data values seen in the input at some earlier moment in time, and (ii) variables that track past choices made within the transition rules. Basically, it is not important when exactly in the past a certain input has been read or when a choice has been made, because only the relation between the values of these and the current variables determines the future behavior of the automaton. Quantifying these variables existentially does the job of ignoring when exactly in the past these values have been seen. Moreover, the last point of Lemma 7 ensures that the refined path is safe in the new unfolding and will stay safe in all future refinements of this unfolding.

The last ingredient of the lazy annotation semi-algorithm based on unfoldings consist in the implementation of the coverage check, when the unfolding of an automaton is labeled with conjunctions of existentially quantified formulae with predicate symbols, obtained from interpolation. By Definition 3, checking whether a given node $\alpha \in \mathrm{dom}(U)$ is covered amounts to finding a prefix $\alpha' \preceq \alpha$ and a node $\beta \in \mathrm{dom}(U)$ such that $U(\alpha') \models U(\beta)$, or equivalently, the formula $U(\alpha') \wedge \neg U(\beta)$ is unsatisfiable. However, the latter formula, in prenex form, has quantifier prefix in the language $\exists^*\forall^*$ and, as previously mentioned, the satisfiability problem for such formulae becomes undecidable when the data theory subsumes Presburger arithmetic [9].

Nevertheless, if we require just a yes/no answer (i.e. not an interpolant) recently developped quantifier instantiation heuristics [23] perform rather well in answering a large number of queries in this class. Observe, moreover, that coverage does not need to rely on a complete decision procedure. If the prover fails in answering the above satisfiability query, then the semi-algorithm assumes that the node is not covered and continues exploring its successors. Failure to compute complete coverage may lead to divergence (non-termination) and ultimately, to failure to prove emptiness, but does not affect the soundness of the semi-algorithm (real counterexamples will still be found).

5 Experimental Results

We have implemented a version of the IMPACT semi-algorithm [18] in a prototype tool, avaliable online[5]. The tool is written in Java and uses the Z3 SMT solver [25], via

[5] HTTPS://GOFILE.IO/?C=WGZ2QE

the JavaSMT interface [13], for spuriousness and coverage queries and also for interpolant generation. Table 1 reports the size of the input automaton in bytes, the numbers of Predicates, Variables and Transitions, the result of emptiness check, the number of Expanded and Visited Nodes during the unfolding and the Time in miliseconds. The experiments were carried out on a MacOS x64 - 1.3 GHz Intel Core i5 - 8 GB 1867 MHz LPDDR3 machine.

Table 1. Experiments with First Order Alternating Automata

The test cases shown in Table 1, come from several sources, namely predicate automata models (*.pa) [5,6] available online [21], timed automata inclusion problems (`abp.ada`, `train.ada`, `rr-crossing.foada`), array logic entailments (`array_rotation.ada`, `array_simple.ada`, `array_shift.ada`) and hardware circuit verification (`hw1.ada`, `hw2.ada`), initially considered in [11], with the restriction that local variables are made visible in the input. The `train-simpleN. foada` and `fischer-mutexN. foada` examples are parametric verification problems in which one checks inclusions of the form $\bigcap_{i=1}^{N} \mathcal{L}(A_i) \subseteq \mathcal{L}(B)$, where A_i is the i-th copy of the same template automaton.

The advantage of using FOADA over the INCLUDER [10] tool from [11] is the possibility of having automata over infinite alphabets with local variables, whose values are not visible in the input. In particular, this is essential for checking inclusion of timed automata that use internal clocks to control the computation.

6 Conclusions

We present first order alternating automata, a model of computation that generalizes classical boolean alternating automata to first order theories. Due to their expressivity, first order alternating automata are closed under union, intersection and complement. However the emptiness problem is undecidable even in the most simple case, of the quantifier-free theory of equality with uninterpreted predicate symbols. We deal with the emptiness problem by developping a practical semi-algorithm that always terminates, when the automaton is not empty. In case of emptiness, termination of the semi-algorithm occurs in most practical test cases, as shown by a number of experiments.

Algorithm 1 IMPACT-based Semi-algorithm for First Order Alternating Automata

input: a first order alternating automaton $\mathcal{A} = \langle \Sigma, X, Q, \iota, F, \Delta \rangle$
output: $\top$ if $L(\mathcal{A}) = \emptyset$, or word $w \in L(\mathcal{A})$, otherwise
data structures: `WorkList` and unfolding tree $\mathcal{U} = \langle N, E, \mathtt{r}, U, \lhd \rangle$, where:
- N is a set of nodes,
- $E \subseteq N \times \Sigma \times N$ is a set of edges labeled by input events,
- $U : N \to \mathsf{Form}^{+}(Q, \emptyset)$ is a labeling of nodes with positive sentences
- $\lhd \subseteq N \times N$ is a coverage relation,

initially `WorkList` $= \{\mathtt{r}\}$ and $N = E = U = \lhd = \emptyset$.

1: **while** `WorkList` $\neq \emptyset$ **do**
2: dequeue n from `WorkList`
3: $N \leftarrow N \cup \{n\}$
4: let $\alpha(n)$ be $a_1, \ldots, a_k$
5: **if** $\overline{\Upsilon}(\alpha)(X^{(1)}, \ldots, X^{(k)})$ is satisfiable **then** ▷ counterexample is feasible
6: get model ν of $\overline{\Upsilon}(\alpha)(X^{(1)}, \ldots, X^{(k)})$
7: **return** $w = (a_1, \nu(X^{(1)})) \ldots (a_k, \nu(X^{(k)}))$ ▷ $w \in L(\mathcal{A})$ by construction
8: **else** ▷ spurious counterexample
9: let $(I_0, \ldots, I_k)$ be a GLI for α
10: $b \leftarrow \bot$
11: **for** $i = 0, \ldots, k$ **do**
12: **if** $U(n_i) \not\models I_i$ **then**
13: $\mathit{Uncover} \leftarrow \{m \in N \mid (m, n_i) \in \lhd\}$
14: $\lhd \leftarrow \lhd \setminus \{(m, n_i) \mid m \in \mathit{Uncover}\}$ ▷ uncover the nodes covered by n_i
15: **for** $m \in \mathit{Uncover}$ such that m is a leaf of $\mathcal{U}$ **do**
16: enqueue m into `WorkList` ▷ reactivate uncovered leaves
17: $U(n_i) \leftarrow U(n_i) \wedge J_i$ ▷ strenghten the label of n_i (Lemma 7)
18: **if** $\neg b$ **then**
19: $b \leftarrow \textsc{Close}(n_i)$
20: **if** n is not covered **then**
21: **for** $a \in \Sigma$ **do** ▷ expand n
22: let s be a fresh node and $e = (n, a, s)$ be a new edge
23: $E \leftarrow E \cup \{e\}$
24: $U \leftarrow U \cup \{(s, \top)\}$
25: enqueue s into `WorkList`
26: **return** $\top$

A Emptiness Checking for First Order Alternating Automata

The execution of Algorithm 1 consists of three phases, corresponding to the Close, Refine and Expand of the original IMPACT procedure [18]. Let n be a node removed from the worklist at line 2 and let $\alpha(n)$ be the input sequence labeling the path from the root node to n. If $\overline{\Upsilon}(\alpha(n))$ is satisfiable, the sequence $\alpha(n)$ is feasible, in which case a model of $\overline{\Upsilon}(\alpha(n))$ is obtained and a word $w \in L(\mathcal{A})$ is returned. Otherwise, $\alpha(n)$ is an infeasible input sequence and the procedure enters the refinement phase (lines 9-19).

Algorithm 2 The Close function from Algorithm 1

```
1: function Close(x) returns 𝔹
2:     for y ∈ N such that α(y) ≺* α(x) do
3:         if U(x) ⊨ U(y) then
4:             ◁ ← [◁ \ {(p,q) ∈ ◁ | q is x or a successor of x}] ∪ {(x,y)}
5:             return ⊤
6:     return ⊥
```

The GLI for $\alpha(n)$ is used to strenghten the labels of all the ancestors of n, by conjoining the formulae of the interpolant, changed according to Lemma 7, to the existing labels.

In this process, the nodes on the path between $\mathtt{r}$ and n, including n, might become eligible for coverage, therefore we attempt to close each ancestor of n that is impacted by the refinement (line 19). Observe that, in this case the call to Close must uncover each node which is covered by a successor of n (line 4 of the Close function). This is required because, due to the over-approximation of the sets of reachable configurations, the covering relation is not transitive, as explained in [18]. If Close adds a covering edge (n_i, m) to $\lhd$, it does not have to be called for the successors of n_i on this path, which is handled via the boolean flag b. Finally, if n is still uncovered (it has not been previously covered during the refinement phase) we expand n (lines 21-25) by creating a new node for each successor s via the input event $a \in \Sigma$ and inserting it into the worklist.

B Proofs of the Technical Results in the Paper

B.1 Proof of Lemma 1

"$\subseteq$" Let $\mathcal{I}$ be a minimal interpretation such that $\mathcal{I}, w_{\mathbb{D}} \models \Theta(w_\Sigma)$. We show that there exists an execution $\mathcal{T}$ of $\mathcal{A}$ over w such that $\mathcal{I} = \mathcal{I}_\mathcal{T}$, by induction on $n \geq 0$. For $n = 0$, we have $w = \epsilon$ and $\Theta(w_\Sigma) = \iota^{(0)}$. Because ι is a sentence, the valuation $w_{\mathbb{D}}$ is not important in $\mathcal{I}, w_{\mathbb{D}} \models \iota^{(0)}$ and, moreover, since $\mathcal{I}$ is minimal, we have $\mathcal{I} \in [\![\iota^{(0)}]\!]^\mu$. We define the interpretation $\mathcal{J}(q) = \mathcal{I}(q^{(0)})$, for all $q \in Q$. Then $\mathtt{c}(\mathcal{J})$ is an execution of $\mathcal{A}$ over ϵ and $\mathcal{I} = \mathcal{I}_{\mathtt{c}(\mathcal{J})}$ is immediate. For the inductive case $n > 0$, we assume that $w = u \cdot (a_n, \nu_n)$ for a word u. Let $\mathcal{J}$ be the interpretation defined as $\mathcal{I}$ for all $q^{(i)}$, with $q \in Q$ and $i \in [n-1]$, and $\emptyset$ everywhere else. Then $\mathcal{J}, u_{\mathbb{D}} \models \Theta(u_\Sigma)$ and $\mathcal{J}$ is moreover minimal. By the induction hypothesis, there exists an execution $\mathcal{G}$ of $\mathcal{A}$ over u, such that $\mathcal{J} = \mathcal{I}_\mathcal{G}$. Consider a leaf of a tree $T \in \mathcal{G}$, labeled with a configuration $q(d_1, \ldots, d_{\#(q)})$ and let $\forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(n-1)}(\mathbf{y}) \rightarrow \psi^{(n)}$ be the subformula of $\Theta(w_\Sigma)$ corresponding to the application(s) of the transition rule $q(\mathbf{y}) \xrightarrow{a_n} \psi$ at the $(n-1)$-th step. Let $\nu = w_{\mathbb{D}}[y_1 \leftarrow d_1, \ldots, y_{\#(q)} \leftarrow d_{\#(q)}]$. Because $\mathcal{I}, w_{\mathbb{D}} \models \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(n-1)}(\mathbf{y}) \rightarrow \psi^{(n)}$, we have $\mathcal{I} \in [\![\psi^{(n)}]\!]_\nu$ and let $\mathcal{K}$ be one of the minimal interpretations such that $\mathcal{K} \subseteq \mathcal{I}$ and $\mathcal{K} \in [\![\psi^{(n)}]\!]_\nu$. It is not hard to see that $\mathcal{K}$ exists and is unique, otherwise we could take the pointwise intersection of two or more such interpretations. We define the interpretation $\overline{\mathcal{K}}(q) = \overline{\mathcal{K}}(q^{(n)})$ for all $q \in Q$. We have that $\overline{\mathcal{K}} \in [\![\psi]\!]^\mu_\nu$ — if $\overline{\mathcal{K}}$ was not minimal, $\mathcal{K}$ was not minimal to start with, contradiction. Then we extend the execution $\mathcal{G}$ by appending to each node labeled with a configuration $q(d_1, \ldots, d_{\#(q)})$ the cube $\mathtt{c}(\overline{\mathcal{K}})$. By repeating this step for all leaves of a tree in $\mathcal{G}$, we obtain an execution of $\mathcal{A}$ over w.

"$\supseteq$" Let $\mathcal{T}$ be an execution of $\mathcal{A}$ over w. We show that $\mathcal{I}_\mathcal{T}$ is a minimal interpretation such that $\mathcal{I}_\mathcal{T}, w_\mathbb{D} \models \Theta(w_\Sigma)$, by induction on $n \geq 0$. For $n = 0$, $\mathcal{T}$ is a cube from $\mathsf{c}([\![\iota]\!]^\mu)$, by definition. Then $\mathcal{I}_\mathcal{T} \models \iota^{(0)}$ and moreover, it is a minimal such interpretation. For the inductive case $n > 0$, let $w = u \cdot (a_n, \nu_n)$ for a word u. Let $\mathcal{G}$ be the restriction of $\mathcal{T}$ to u. Consequently, $\mathcal{I}_\mathcal{G}$ is the restriction of $\mathcal{I}_\mathcal{T}$ to $Q^{(\leq n-1)}$. By the inductive hypothesis, $\mathcal{I}_\mathcal{G}$ is a minimal interpretation such that $\mathcal{I}_\mathcal{G}, u_\mathbb{D} \models \Theta(u_\Sigma)$. Since $\mathcal{I}_\mathcal{T}(q^{(n)}) = \{\langle d_1, \ldots, d_{\#(q)}\rangle \mid q(d_1, \ldots, d_{\#(q)}) \text{ labels a node on the } n\text{-th level in } \mathcal{T}\}$, we have $\mathcal{I}_\mathcal{T}, w_\mathbb{D} \models \varphi$, for each subformula $\varphi = \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(n-1)}(\mathbf{y}) \rightarrow \psi^{(n)}$ of $\Theta(w_\Sigma)$, by the execution semantics of $\mathcal{A}$. This is the case because the children of each node labeled with $q(d_1, \ldots, d_{\#(q)})$ on the $(n-1)$-th level of $\mathcal{T}$ form a cube from $\mathsf{c}([\![\psi]\!]^\mu_\nu)$, where ν is a valuation that assigns each y_i the value d_i and behaves like $w_\mathbb{D}$, otherwise. Now suppose, for a contradiction, that $\mathcal{I}_\mathcal{T}$ is not minimal and let $\mathcal{J} \subsetneq \mathcal{I}_\mathcal{T}$ be an interpretation such that $\mathcal{J}, w_\mathbb{D} \models \Theta(w_\Sigma)$. First, we show that the restriction $\mathcal{J}'$ of $\mathcal{J}$ to $\bigcup_{i=0}^{n-1} Q^{(i)}$ must coincide with $\mathcal{I}_\mathcal{G}$. Assuming this is not the case, i.e. $\mathcal{J}' \subsetneq \mathcal{I}_\mathcal{G}$, contradicts the minimality of $\mathcal{I}_\mathcal{G}$. Then the only possibility is that $\mathcal{J}(q^{(n)}) \subsetneq \mathcal{I}_\mathcal{T}(q^{(n)})$, for some $q \in Q$. Let $p_1(y_1, \ldots, y_{\#(p_1)}) \xrightarrow{a_n} \psi_1, \ldots, p_k(y_1, \ldots, y_{\#(p_k)}) \xrightarrow{a_n} \psi_k$ be the set of transition rules in which the predicate symbol q occurs on the right-hand side. Then it must be the case that, for some node on the $(n-1)$-th level of $\mathcal{G}$, labeled with a configuration $p_i(d_1, \ldots, d_{\#(p_i)})$, the set of children does not form a minimal cube from $\mathsf{c}([\![{\psi_i}^{(n)}]\!]^\mu)$, which contradicts the execution semantics of $\mathcal{A}$. □

B.2 Proof of Lemma 2

"(1) ⇒ (2)" Let $\mathcal{I}$ be an interpretation such that $\mathcal{I}, w_\mathbb{D} \models \Upsilon(w_\Sigma)$. By Lemma 1, $\mathcal{A}$ has an execution $\mathcal{T}$ over w such that $\mathcal{I} = \mathcal{I}_\mathcal{T}$. To prove that $\mathcal{T}$ is accepting, we show that (i) all paths in $\mathcal{T}$ have length n and that (ii) the frontier of $\mathcal{T}$ is labeled with final configurations only. First, assume that (i) there exists a path in $\mathcal{T}$ of length $0 \leq m < n$. Then there exists a node on the m-th level, labeled with some configuration $q(d_1, \ldots, q_{\#(q)})$, that has no children. By the definition of the execution semantics of $\mathcal{A}$, we have $\mathsf{c}([\![\psi]\!]^\mu_\eta) = \emptyset$, where $q(\mathbf{y}) \xrightarrow{a_{m+1}(X)} \psi$ is the transition rule of $\mathcal{A}$ that applies for q and a_{m+1} and $\eta = w_\mathbb{D}[y_1 \leftarrow d_1, \ldots, y_{\#(q)} \leftarrow d_{\#(q)}]$. Hence $[\![\psi]\!]_\eta = \emptyset$, and because $\mathcal{I}, w_\mathbb{D} \models \Upsilon(\alpha)$, we obtain that $\mathcal{I}, \eta \models q(\mathbf{y}) \rightarrow \psi^{(m+1)}$, thus $\langle d_1, \ldots, d_{\#(q)}\rangle \notin \mathcal{I}(q)$. However, this contradicts the fact that $\mathcal{I} = \mathcal{I}_\mathcal{T}$ and that $q(d_1, \ldots, d_{\#(q)})$ labels a node of $\mathcal{T}$. Second, assume that (ii), there exists a frontier node of $\mathcal{T}$ labeled with a configuration $q(d_1, \ldots, d_{\#(q)})$ such that $q \in Q \setminus F$. Since $\mathcal{I}, w_\mathbb{D} \models \forall y_1 \ldots \forall y_{\#(q)} \,.\, q(\mathbf{y}) \rightarrow \bot$, by a similar reasoning as in the above case, we obtain that $\langle d_1, \ldots, d_{\#(q)}\rangle \notin \mathcal{I}(q)$, contradiction.

"(2) ⇒ (1)" Let $\mathcal{T}$ be an accepting execution of $\mathcal{A}$ over w. We prove that $\mathcal{I}_\mathcal{T}, w_\mathbb{D} \models \Upsilon(w_\Sigma)$. By Lemma 1, we obtain $\mathcal{I}_\mathcal{T}, w_\mathbb{D} \models \Theta(w_\Sigma)$. Since every path in $\mathcal{T}$ is of length n and all nodes on the n-th level of $\mathcal{T}$ are labeled by final configurations, we obtain that $\mathcal{I}_\mathcal{T}, w_\mathbb{D} \models \bigwedge_{q \in Q \setminus F} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(n)}(\mathbf{y}) \rightarrow \bot$, trivially. □

B.3 Proof of Lemma 3

(1) Trivial, since every subformula $q(t_1, \ldots, t_{\#(q)}) \rightarrow \psi[t_1/y_1, \ldots, t_{\#(q)}/y_{\#(q)}]$ of $\widehat{\Upsilon}(\alpha)$ is entailed by a subformula $\forall y_1 \ldots \forall y_{\#(q)} \,.\, q(y_1, \ldots, y_{\#(q)}) \rightarrow \psi$ of $\Upsilon(\alpha)$.
(2) By repeated applications of the following fact:

Fact 2 *Given formulae ϕ and ψ, such that no predicate atom with predicate symbol q occurs in $\psi(y_1,\dots,y_{\#(q)})$, for each valuation ν, if there exists an interpretation $\mathcal{I}$ such that $\mathcal{I},\nu \models \phi \wedge \bigwedge_{q(t_1,\dots,t_{\#(q)}) \text{ occurs in } \phi} q(t_1,\dots,t_{\#(q)}) \rightarrow \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$ then there exists a valuation $\mathcal{J}$ such that $\mathcal{J}(q) \subseteq \mathcal{I}(q)$ and $\mathcal{J}(q') = \mathcal{I}(q')$ for all $q' \in Q \setminus \{q\}$ and $\mathcal{J},\nu \models \phi \wedge \forall y_1 \dots \forall y_{\#(q)} \,.\, q(y_1,\dots,y_{\#(q)}) \rightarrow \psi$.*

Proof. Assume w.l.o.g. that ϕ is quantifier-free. The proof can be easily generalized to the case ϕ has quantifiers. Let $\mathcal{J}(q) = \{\langle t_1^\nu,\dots,t_{\#(q)}^\nu\rangle \in \mathcal{I}(q) \mid q(t_1,\dots,t_{\#(q)}) \text{ occurs in } \phi\}$ and $\mathcal{J}(q') = \mathcal{I}(q')$ for all $q' \in Q \setminus \{q\}$. Since $\mathcal{I},\nu \models \phi$, we obtain that also $\mathcal{J},\nu \models \phi$ because the tuples of values in $\mathcal{I}(q) \setminus \mathcal{J}(q)$ are not interpretations of terms that occur within subformulae $q(t_1,\dots,t_{\#(q)})$ of ϕ. Moreover, $\bigwedge_{q(t_1,\dots,t_{\#(q)}) \text{ occurs in } \phi} q(t_1,\dots,t_{\#(q)}) \rightarrow \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$ and $\forall y_1 \dots \forall y_{\#(q)} \,.\, q(y_1,\dots,y_{\#(q)}) \rightarrow \psi$ are equivalent under $\mathcal{J}$, thus $\mathcal{J},\nu \models \forall y_{\#(q)} \,.\, q(y_1,\dots,y_{\#(q)}) \rightarrow \psi$, as required. □
This concludes the proof of Lemma 3. □

B.4 Proof of Lemma 4

By induction on $n \geq 0$. The base case $n = 0$ is trivial, since $\widehat{\Upsilon}(A) = \overline{\Upsilon}(A) = \iota^{(0)}$. For the induction step, we rely on the following fact:

Fact 3 *Given formulae ϕ and ψ, such that ϕ is positive $q(t_1,\dots,t_{\#(q)})$ is the only one occurrence of the predicate symbol q in ϕ and no predicate atom with predicate symbol q occurs in $\psi(y_1,\dots,y_{\#(q)})$, for each interpretation $\mathcal{I}$ and each valuation ν, we have:*

$$\mathcal{I},\nu \models \phi \wedge q(t_1,\dots,t_{\#(q)}) \rightarrow \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}] \Leftrightarrow$$
$$\nu \models \phi[\psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]/q(t_1,\dots,t_{\#(q)})] \;.$$

Proof. We assume w.l.o.g. that ϕ is quantifier-free. The proof can be easily generalized to the case ϕ has quantifiers.
"⇒" We distinguish two cases:

- if $\langle t_1^\nu,\dots,t_{\#(q)}^\nu\rangle \in \mathcal{I}(q)$ then $\mathcal{I},\nu \models \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$. Since ϕ is positive, replacing $q(t_1,\dots,t_{\#(q)})$ with $\psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$ does not change the truth value of ϕ under ν, thus $\nu \models \phi[\psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]/q(t_1,\dots,t_{\#(q)})]$.
- else, $\langle t_1^\nu,\dots,t_{\#(q)}^\nu\rangle \notin \mathcal{I}(q)$, thus $\nu \models \phi[\bot/q(t_1,\dots,t_{\#(q)})]$. Since ϕ is positive and $\bot$ entails $\psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$, we obtain $\nu \models \phi[\psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]/q(t_1,\dots,t_{\#(q)})]$ by monotonicity.

"⇐" Let $\mathcal{I}$ be any interpretation such that $\mathcal{I}(q) = \{\langle t_1^\nu,\dots,t_{\#(q)}^\nu\rangle \mid \nu \models \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]\}$.
We distinguish two cases:

- if $\mathcal{I}(q) \not\emptyset$ then $\mathcal{I},\nu \models q(t_1,\dots,t_{\#(q)})$ and $\nu \models \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$. Thus replacing $\psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$ by $q(t_1,\dots,t_{\#(q)})$ does not change the truth value of ϕ under $\mathcal{I}$ and ν, and we obtain $\mathcal{I},\nu \models \phi$. Moreover, $\mathcal{I},\nu \models \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$ implies $\mathcal{I},\nu \models q(t_1,\dots,t_{\#(q)}) \rightarrow \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$.
- else $\mathcal{I}(q) = \emptyset$, hence $\nu \not\models \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$, thus $\nu \models \phi[\bot/q(t_1,\dots,t_{\#(q)})]$. Because ϕ is positive, we obtain $\mathcal{I},\nu \models \phi$ by monotonicity. But $\mathcal{I},\nu \models q(t_1,\dots,t_{\#(q)}) \rightarrow \psi[t_1/y_1,\dots,t_{\#(q)}/y_{\#(q)}]$ trivially, because $\mathcal{I},\nu \not\models q(t_1,\dots,t_{\#(q)})$. □

This concludes the proof of Lemma 4. □

B.5 Proof of Lemma 5

By Lemma 2, $w \in \mathcal{L}(\mathcal{A})$ if and only if $\mathcal{I}, w_{\mathbb{D}} \models \Upsilon(w_\Sigma)$, for some interpretation $\mathcal{I}$. By Lemma 3, there exists an interpretation $\mathcal{I}$ such that $\mathcal{I}, w_{\mathbb{D}} \models \Upsilon(w_\Sigma)$ if and only if there exists an interpretation $\mathcal{J}$ such that $\mathcal{J}, \nu \models \widehat{\Upsilon}(w_\Sigma)$. By Lemma 4, there exists an interpretation $\mathcal{J}$ such that $\mathcal{J}, \nu \models \widehat{\Upsilon}(w_\Sigma)$ if and only if $\nu \models \overline{\Upsilon}(w_\Sigma)$. □

B.6 Proof of Theorem 2

Let U be a safe and complete unfolding of $\mathcal{A}$, such that $\mathrm{dom}(U) \neq \emptyset$. Suppose, by contradiction, that there exists a word $w \in \mathcal{L}(A)$ and let $\alpha \stackrel{\mathsf{def}}{=} w_\Sigma$. Since $w \in \mathcal{L}(A)$, by Lemma 2, there exists an interpretation $\mathcal{I}$ such that $\mathcal{I}, w_{\mathbb{D}} \models \Upsilon(\alpha)$. Assume first that $\alpha \in \mathrm{dom}(U)$. In this case, one can show, by induction on the length $n \geq 0$ of w, that $\Theta(\alpha) \models U(\alpha)^{(n)}$, thus $\mathcal{I}, w_{\mathbb{D}} \models U(\alpha)^{(n)}$. Since $\mathcal{I}, w_{\mathbb{D}} \models \Upsilon(\alpha)$, we have $\mathcal{I}, w_{\mathbb{D}} \models \bigwedge_{q \in Q \setminus F} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(n)}(\mathbf{y}) \rightarrow \bot$, hence $U(\alpha)^{(n)} \wedge \bigwedge_{q \in Q \setminus F} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(n)}(\mathbf{y}) \rightarrow \bot$. By renaming $q^{(n)}$ with q in the previous formula, we obtain $U(\alpha) \wedge \forall y_1 \ldots \forall y_{\#(q)} \,.\, q(\mathbf{y}) \rightarrow \bot$ is satisfiable, thus U is not safe, contradiction.

We proceed thus under the assumption that $\alpha \notin \mathrm{dom}(U)$. Since $\mathrm{dom}(U)$ is a nonempty prefix-closed set, there exists a strict prefix α' of α that is a leaf of $\mathrm{dom}(U)$. Since U is closed, the leaf α' must be covered and let $\alpha_1 \preceq \alpha' \preceq \alpha$ be a node such that $U(\alpha_1) \models U(\beta_1)$, for some uncovered node $\beta_1 \in \mathrm{dom}(U)$. Let γ_1 be the unique sequence such that $\alpha_1\gamma_1 = \alpha$. By Definition 3, since $\alpha_1 \sqsubseteq \beta_1$ and $w_\Sigma = \alpha_1\gamma_1 \in \mathcal{L}(\mathcal{A})$, there exists a word w_1 and a cube $c_1 \in \mathsf{c}([\![U(\alpha_1)]\!]) \subseteq \mathsf{c}([\![U(\beta_1)]\!])$, such that $w_{1\Sigma} = \gamma_1$ and $\mathcal{A}$ accepts w_1 starting with c_1. If $\beta_1\gamma_1 \in \mathrm{dom}(U)$, we obtain a contradiction by a similar argument as above. Hence $\beta_1\gamma_1 \notin \mathrm{dom}(U)$ and there exists a leaf of $\mathrm{dom}(U)$ which is also a prefix of $\beta_1\gamma_1$. Since U is closed, this leaf is covered by an uncovered node $\beta_2 \in \mathrm{dom}(U)$ and let $\alpha_2 \in \mathrm{dom}(U)$ be the minimal (in the prefix partial order) node such that $\beta_1 \preceq \alpha_2 \preceq \beta_1\gamma_1$ and $\alpha_2 \sqsubseteq \beta_2$. Let γ_2 be the unique sequence such that $\alpha_2\gamma_2 = \beta_1\gamma_1$. Since β_1 is uncovered, we have $\beta_1 \neq \alpha_2$ and thus $|\gamma_1| > |\gamma_2|$. By repeating the above reasoning for α_2, β_2 and γ_2, we obtain an infinite sequence $|\gamma_1| > |\gamma_2| > \ldots$, which is again a contradiction. □

B.7 Proof of Lemma 6

(1) If $\Upsilon(\alpha)$ is unsatisfiable, by Lemmas 3 and 4, we obtain that, successively $\widehat{\Upsilon}(\alpha)$ and $\overline{\Upsilon}(\alpha)$ are unsatisfiable. Let $Q_1x_1 \ldots Q_mx_m \,.\, \widehat{\Phi}$ and $Q_1x_1 \ldots Q_mx_m \,.\, \overline{\Phi}$ be prenex forms for $\widehat{\Upsilon}(\alpha)$ and $\overline{\Upsilon}(\alpha)$, respectively. Since we assumed that the first order theory of the data domain has witness-producing quantifier elimination, using Theorem 3 one can effectively build witness terms $\tau_{i_1}, \ldots, \tau_{i_\ell}$, where $\{i_1, \ldots, i_\ell\} = \{i \in [1,m] \mid Q_i = \forall\}$ and:

- $\mathrm{V}(\tau_{i_j}) \subseteq X^{(\leq \xi(i_j))} \cup \{x_k \mid k < i_j, Q_k = \exists\}$, for all $j \in [1,\ell]$ and
- $\overline{\Phi}[\tau_{i_1}/x_{i_1}, \ldots, \tau_{i_\ell}/x_{i_\ell}]$ is unsatisfiable.

Let $\widehat{\Phi}_0, \ldots, \widehat{\Phi}_n$ be the sequence of quantifier-free formulae, defined as follows:

- $\widehat{\Phi}_0$ is the matrix of some prenex form of $\iota^{(0)}$,

– for all $i = 1, \ldots, n$, let $\widehat{\Phi}_i$ be the matrix of some prenex form of:

$$\widehat{\Phi}_i \stackrel{\text{def}}{=} \widehat{\Phi}_{i-1} \wedge \underbrace{\bigwedge_{\substack{q^{(i-1)}(t_1,\ldots,t_{\#(q)}) \text{ occurs in } \widehat{\Phi}_{i-1} \\ q(y_1,\ldots,y_{\#(q)}) \xrightarrow{a_i(X)} \psi \in \Delta}} q^{(i-1)}(t_1,\ldots,t_{\#(q)}) \rightarrow \psi^{(i)}[t_1/y_1,\ldots,t_{\#(q)}/y_{\#(q)}]}_{\stackrel{\text{def}}{=} \phi_i}$$

It is easy to see that $\widehat{\Phi}$ is the matrix of some prenex form of:

$$\widehat{\Phi}_n \wedge \underbrace{\bigwedge_{\substack{q^{(n)}(t_1,\ldots,t_{\#(q)}) \text{ occurs in } \widehat{\Phi}_n \\ q \in Q \setminus F}} q^{(n)}(t_1,\ldots,t_{\#(q)}) \rightarrow \bot}_{\stackrel{\text{def}}{=} \psi}$$

Applying the equivalence from Fact 3 in the proof of Lemma 4, we obtain a sequence of quantifier-free formulae $\overline{\Phi}_0, \ldots, \overline{\Phi}_n$ such that $\overline{\Phi}_i \equiv \widehat{\Phi}_i$, for all $i \in [n]$ and $\overline{\Phi}$ is obtained from $\overline{\Phi}_n$ by replacing each occurrence of a predicate atom $q(t_1,\ldots,t_{\#(q)})$ in $\overline{\Phi}_n$ by $\bot$ if $q \in Q \setminus F$ and by $\top$ if $q \in F$. Clearly $\overline{\Phi} \equiv \widehat{\Phi}$, thus $\widehat{\Phi}[\tau_{i_1}/x_{i_1},\ldots,\tau_{i_\ell}/x_{i_\ell}] \equiv \overline{\Phi}[\tau_{i_1}/x_{i_1},\ldots,\tau_{i_\ell}/x_{i_\ell}] \equiv \bot$.

(2) With the notation introduced at point (1), we have $\widehat{\Phi} = \widehat{\Phi}_0 \wedge \bigwedge_{i=1}^{n} \phi_i \wedge \psi$. Consider the sequence of witness terms $\tau_{i_1}, \ldots, \tau_{i_\ell}$, whose existence is proved by point (1). Because $\mathrm{V}(\tau_{i_j}) \subseteq X^{(\leq \xi(i_j))} \cup \{x_k \mid k < i_j, Q_k = \exists\}$, for all $j \in [1,\ell]$, and moreover ξ^{-1} is strictly monotonic, we obtain:

– $\mathrm{V}(\widehat{\Phi}_0[\tau_{i_1}/x_{i_1},\ldots,\tau_{i_\ell}/x_{i_\ell}]) \subseteq Q^{(0)} \cup X^{(0)} \cup \{x_j \mid j < \xi^{-1}_{\max}(0), Q_j = \exists\}$,
– $\mathrm{V}(\phi_i[\tau_{i_1}/x_{i_1},\ldots,\tau_{i_\ell}/x_{i_\ell}]) \subseteq Q^{(i-1)} \cup Q^{(i)} \cup X^{(\leq i)} \cup \{x_j \mid j < \xi^{-1}_{\max}(i), Q_j = \exists\}$, for all $i \in [1,n]$,
– $\mathrm{V}(\psi[\tau_{i_1}/x_{i_1},\ldots,\tau_{i_\ell}/x_{i_\ell}]) \subseteq Q^{(n)} \cup X^{(\leq n)} \cup \{x_j \mid j \in [1,m], Q_j = \exists\}$.

By repeatedly applying Lyndon's Interpolation Theorem, we obtain a sequence of formulae $(I_0, \ldots, I_n)$ such that:

– $\widehat{\Phi}_0[\tau_{i_1}/x_{i_1},\ldots,\tau_{i_\ell}/x_{i_\ell}] \models I_0$ and $\mathrm{V}(I_0) \subseteq Q^{(0)} \cup X^{(0)} \cup \{x_j \mid j < \xi^{-1}_{\max}(0), Q_j = \exists\}$,
– $I_{k-1} \wedge \phi_i[\tau_{i_1}/x_{i_1},\ldots,\tau_{i_\ell}/x_{i_\ell}] \models I_k$ and $\mathrm{V}(I_k) \subseteq Q^{(k)} \cup X^{(\leq k)} \cup \{x_j \mid j < \xi^{-1}_{\max}(k), Q_j = \exists\}$, for all $k \in [1,n]$,
– $I_n \wedge \psi[\tau_{i_1}/x_{i_1},\ldots,\tau_{i_\ell}/x_{i_\ell}]$ is unsatisfiable.

To show that $(I_0, \ldots, I_n)$ is a GLI for $a_1 \ldots a_n$, it is sufficient to notice that

$$\bigwedge_{q(\mathbf{y}) \xrightarrow{a_k(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(k)}(\mathbf{y}) \rightarrow \psi^{(k+1)} \models \phi_k$$

for all $k \in [1,n]$. Consequently, we obtain:

– $\iota^{(0)} \models \widehat{\Phi}_0 \models I_0$, by Theorem 3,
– $I_{k-1} \wedge \Big(\bigwedge_{q(\mathbf{y}) \xrightarrow{a_k(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(k-1)}(\mathbf{y}) \rightarrow \psi^{(k)} \Big) \models I_{k-1} \wedge \phi_k \models I_k$, and
– $I_n \wedge \Big(\bigwedge_{q \in Q \setminus F} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q(\mathbf{y}) \rightarrow \bot \Big) \models I_n \wedge \psi \models \bot$,

as required by Definition 5. □

B.8 Proof of Lemma 7

The new set of formulae $U'(\alpha_0), \ldots, U'(\alpha_n)$ complies with Definition 2, because:

– $U'(\alpha_0) \equiv \iota$, since, by point 2 of Definition 5, we have $\iota^{(0)} \models I_0$, thus $\iota \models J_0$ and $U'(\alpha_0) = U(\alpha_0) \wedge J_0 \equiv \iota \wedge J_0 \equiv \iota$, and
– by Definition 5 (3) we have, for all $k \in [n-1]$:

$$I_k \wedge \bigwedge_{q(\mathbf{y}) \xrightarrow{a_k(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(k)}(\mathbf{y}) \rightarrow \psi^{(k+1)} \models I_{k+1}$$

We write $I_k^{\langle j \rangle}$ for the formula in which each predicate symbol $q^{(k)}$ is replaced by $q^{(j)}$. Then the following entailment holds:

$$I_k^{\langle 0 \rangle} \wedge \bigwedge_{q(\mathbf{y}) \xrightarrow{a_k(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(0)}(\mathbf{y}) \rightarrow \psi^{(1)} \models I_{k+1}^{\langle 1 \rangle}$$

Because J_k is obtained by removing the time stamps from the predicate symbols and existentially quantifying all the free variables of I_k, we also obtain, applying Fact 4 below:

$$J_k^{(0)} \wedge \bigwedge_{q(\mathbf{y}) \xrightarrow{a_k(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(0)}(\mathbf{y}) \rightarrow \psi^{(1)} \models J_{k+1}^{(1)}$$

Since U satisfies the labeling condition of Definition 2 and $U'(\alpha_k) = U(\alpha_k) \wedge J_k$, we obtain, as required:

$$U'(\alpha_k)^{(0)} \wedge \bigwedge_{q(\mathbf{y}) \xrightarrow{a_k(X)} \psi \in \Delta} \forall y_1 \ldots \forall y_{\#(q)} \,.\, q^{(0)}(\mathbf{y}) \rightarrow \psi^{(1)} \models U'(\alpha_{k+1})^{(1)} \quad .$$

Fact 4 *Given formulae $\phi(\mathbf{x}, \mathbf{y})$ and $\psi(\mathbf{x})$ such that $\phi(\mathbf{x}, \mathbf{y}) \models \psi(\mathbf{x})$, we also have $\exists \mathbf{x} \,.\, \phi(\mathbf{x}, \mathbf{y}) \models \exists \mathbf{x} \,.\, \psi(\mathbf{x})$.*

Proof. For each choice of a valuation for the existentially quantified variables on the left-hand side, we chose the same valuation for the variables on the right-hand side. □
